The learner interaction profiler uses a bidirectional social network graph, which consists of different types of U2U interactions (e.g., replies and reads). Each user is a node in this graph and the interactions among users are edges. In Figure 3, the thin grey link from user U1 to user U2 indicates that U1 has read U2's post.

Students who have many interactions with the active user are their peer learners. The rich interaction history, whether in discussion or debate, indicates the active user's interest in interacting with those peers. This group of users share many outward edges with the active user in the social network graph. The inclusion threshold for number of edges required between users is set via grid search. As a result, the module generates links connecting the active user to those peer learners (the green edges in Figure 2) in the PPR graph.

The analyses over the graph also output a participation level (i.e., number of outgoing edges of reply, like, and link types from its user node) and a degree of centrality (i.e., the in-degree of a node) for each student. The more frequently other students interact with the active user's posts, the more they can increase the active user's degree of centrality. The participation level indicates the extent to which the student is actively engaging in the discussion. We used the two measures to identify four types of learners (new user, listener, single-pass user, and peripheral user) that may need differentiated recommendation strategies. These user types are identified using simple heuristics based on the literature.

Figure 2. The modified PPR graph has 3 node types (user - green, post - red, and hypernym - yellow) and 3 edge types (user-to-user - green, user-to-post - red, and post-to-hypernym - yellow). Edges without arrows are bidirectional and edge width indicates number of occurrences.

¹ Code is available at <https://github.com/EdTeKLA/CSCLRec>

Figure 3. The workflow of the learner interaction profiler. Edge widths in the graph indicate the number of interactions.

New users are learners who have just joined the discussion. They have not created any resources nor do they have any other logged interactions. Consequently, these users are subject to the cold-start problem, which makes it difficult for the algorithms to provide suggestions because of the lack of data [10]. New users may experience greater information overload because they face many posts at once and may need tailored recommendations to help them filter information, identify their interests early, and contribute their own voices. To prevent narrow recommendations, new users are connected to every other user in the PPR graph.

Listeners read many posts but rarely post themselves [86]. The knowledge building principle of collective responsibility and symmetric knowledge advancement suggests that encouraging posting is critical to fostering activity and promoting knowledge co-construction [69]. Listeners are identified as those who have not created posts. To reduce the number of persistent listeners, we adopt the same recommendation strategy as that employed for new users since exposing these learners to different topics may increase the possibility of their expressing opinions [46].

Peripheral users are those whose centrality score is decreasing due to lost interactivity in their readership. The module aims to recover peripheral users and listeners to promote the knowledge-sharing process [47, 48] and prevent the loss of these readers' activity and interest. The learner profiler monitors the number of interactive readers for each learner: those who reply, like, or link. When the profiler detects the user's interactive reader count has dropped by half from one week to the next, that user is marked as a peripheral user. This value was tuned during the evaluation. The algorithm takes note of the lost readers and introduces connections between the peripheral user and the lost readers in the PPR graph to strengthen their connections.

Single-pass users only read new posts and ignore older posts [38]. Their widespread presence undermines socio-collaborative learning approaches because these learning processes require topics to be progressively discussed and deepened [69]. To alleviate this behavior, some have suggested encouraging students to revisit earlier posts [38]. Inspired by this idea, the learner interaction profiler identifies students who have only read posts from the previous week. For example, those who have not read posts created before week 7 are marked as single-pass users in week 8. The modified PPR graph decreases the temporal decay exerted on older posts for single-pass users so earlier posts are down-weighted less, increasing the likelihood of their recommendation to these learners.

3.3 Content Analyzer

Forum posts are hierarchically structured. Posts on the same topic have similar interaction records because users are accustomed to browsing the entire topic structure when reading a post. Therefore, algorithms based on interaction records (i.e., collaborative filtering,

Figure 4. The workflow of the content analyzer module

ordinary personalized PageRank bipartite graph) may only recommend posts that are locationally similar to those that users often interact with. Consequently, students may lose the opportunity to read posts that match their current interests because they are located elsewhere. These algorithms also bias towards post popularity [77] causing the “long-tail” problem: unpopular posts are not considered for recommendation [21, 62], which could decrease student exposure to diverse perspectives. To overcome these challenges, the content analyzer module applies natural language processing (NLP) techniques to the content of forum posts and enables links to be created between posts based on the concepts discussed rather than user interactions (as shown in Figure 2). Its workflow is shown in Figure 4. The preprocessing stage removes all html mark-up and punctuation. It also tokenizes sentences into individual words. Lemmas are extracted for nouns and verbs, and stop words are removed. To protect user privacy, person names, usernames, web URLs, and email addresses are also removed. Each post is then organized as a bag-of-words (BoW).

TF-IDF was chosen for keyword extraction following a preliminary evaluation that compared several potential methods (i.e., RAKE [67], TextRank [54]) on independent data from the same system. TF-IDF scores are computed for each lemma to choose keywords that best differentiate the current post from others. The keywords with the top 1/5 TF-IDF scores are used to represent the post.

The extracted keywords are used to measure thematic similarity across posts. Instead of matching keywords using text similarity approaches (i.e., sentence embeddings or topic distribution vectors in vector space models), we consider two posts thematically similar provided they mentioned similar concepts regardless of student opinion towards a topic. The tools used to measure similarity included the WordNet semantic network and its collection of hypernyms [55]. We query each post in WordNet and use Lesk [50] to disambiguate hypernyms. The hypernyms are added as nodes in the PPR graph - see the yellow nodes in Figure 2. When a post contains a keyword that belongs to this hypernym, a link from the post node to the hypernym node is constructed. As a result, posts that share more concepts will share more hypernym nodes.

3.4 Post Filtering

This module analyzes, sorts, filters, and re-ranks the results produced by the recommender which may otherwise include less-informative posts that will not advance student knowledge. Posts like, “Thank you for the clarification, [name]” may be output by the algorithm if this filtering is not performed. The post filtering module refines the recommendations using two filters: one extracts verb and noun phrases as trigram models and excludes posts with fewer than 3 phrases, and the other compares post content with the Academic Word List (AWL) [20]. Posts with fewer than 3 AWL words are removed.

4. METHODS

We evaluated the performance of CSCLRec, its precursor, and other widely-used algorithms using a similar protocol to that advised by recommender system researchers [28, 73]. In each week, we recommend 10 posts to each user. Posts were selected from a candidate list consisting of those the active user has not yet read and all posts created by others in the current (evaluation) week. We hide this user's activities from the evaluation week and use forum

Table 1. Student and instructor interactions through the course forum as a raw count (#) or $M(SD)$.

Course	Weeks (#)	Students (#)	Instructors (#)	Posts (#)	Interacted posts/ student	Interactions/ student	Reads/ student	Likes/ student	Links/ student

activities from prior weeks to train the recommenders. We start from week 2 since there are no learner posts prior to week 1.

4.1 Dataset

The evaluation used historical data from six postgraduate courses offered through an asynchronous discussion platform (PeppeR) at the University of Toronto. PeppeR provides a collaborative learning space to discuss and share ideas, making this system an ideal testbed to evaluate the proposed recommender system.

Archival data from fully online courses were used. Of the six test courses, three were regular-length courses (13-weeks long) and the others were short courses (6-weeks long). User activity statistics for each course are summarized in Table 1. The data includes forum posts and all kinds of user interactions with posts (i.e., posting, replying to others' posts, inserting hyperlinks to other posts, liking posts, and reading posts). The interactions were categorized into 7 types: create, reply, like, link, revisit, read, and anonymously read.

The large variability in student interactions (see Table 1) is consistent with the different types of users identified: Some had many forum activities, while others seldom interacted with posts. This suggests the necessity of distinguishing different learner types and employing user-specific recommendation strategies.

4.2 Recommender Algorithms

CSCLRec's performance was compared against that of 7 other recommenders. Due to the limited number of students, the diversity of student interaction behaviors, and the inter-dependence of time-series data, random cross validation was not appropriate. We tuned the hyperparameters using last block validation [9]: For each weekly evaluation, we used the prior week to validate the current weeks' recommendations. We used grid-search on the hyperparameters and trained the recommenders using data from before the validation week. Testing used data from the validation week. Using precision, the best performing hyperparameters were selected to build the recommenders for subsequent evaluations. For CSCLRec, we tuned temporal decay and the number of peer learners. All PPR-based algorithms had their damping factor tuned.

The algorithms we tested CSCLRec against are listed below. Hyper-parameter values are reported in the repository¹.

- Co-occurrence graph-based personalized PageRank (**CoPPR**) is another original method we developed. It uses the same learner profiler and post filtering modules as CSCLRec. Different from CSCLRec, Co-PPR uses the extracted keywords as nodes. Two keyword nodes are connected if they co-occurred at least once in a post. A post is connected to a keyword node if that post contains the keyword at least once. Edge weights are determined using the posts' keyword occurrence count. CoPPR helps identify the contribution of the content analyzer to CSCLRec. We tuned temporal decay, the damping factor, and number of peer learners.

- Personalized PageRank (**PPR**) is a widely used graph-based recommender [15, 58]. It uses a bipartite graph with user-to-post interactions as the only input.
- Matrix factorization collaborative filtering (**MCF**) represents a family of model-based collaborative filtering algorithms, which are commonly used in educational recommender systems [27, 78]. We used the version proposed by Hu and colleagues [40]. We tuned its confidence factor which specifies the negative weight attributed to unseen interactions.
- Keyword-based content-based recommender system (**KCB**) is frequently used to personalize discussion forums [4] and help-seeking platforms [52]. KCB relies on latent semantic indexing to create vectors from posts. Users are represented as the average of the post vectors they have interacted with before. It recommends candidate posts which are nearest to the active user in the vector space. The hyperparameters include the dimension of post vectors and the ratio of content words as the keywords (i.e., 1/7 of the content words are treated as keywords).
- Sentence embedding-based content-based recommender (**SCB**) relies on the semantics of post content [16].
- Popularity-based recommender (**PPL**) recommends popular posts. Every user receives the same recommendations. This unpersonalized algorithm is used as a baseline.
- The random recommender (**RND**) randomly draws posts from the candidate list. This algorithm is also used as a baseline.

We did not test all well-known recommendation algorithms as some structural aspects and requirements of the algorithms make them a poor fit given the nature of our dataset. For example, deep learning-based methods (i.e., autoencoders) are data-hungry and can easily overfit due to the size of our dataset [88].

4.3 Measures

Since accuracy is insufficient for determining the quality of educational recommender systems [30], we measured 3 dimensions of performance: accuracy, diversity, and novelty.

For accuracy, we report both Precision at K (**P@K**) and Recall at K (**R@K**), where k is the number of recommendations. The R@K measure is affected by the number of available relevant items [73] so we report the maximum (max) R@10 to aid interpretation. Max R@10 is the average of the largest possible R@10 in each user's recommendations. We adopted the commonly used intra-list diversity (**ILD**) indicator which measures the average pairwise distance between recommended items [14, 76]. We used pre-trained Universal Sentence Encoder [16] embeddings to represent the posts and the cosine distance to compute ILDs. The mean inverse user frequency (**MIUF**) indicator is used to measure recommendation novelty [11]. The fewer people who have interacted with the post, the higher the novelty and IUF of that post. To reflect the consistency of algorithm performance, we report the

Table 2. Summary of evaluation results as $M(SD)$

Algorithm	Long courses (LA, LB, LC)				Short courses (SA, SB, SC)			
	P@10	R@10	ILD	MIUF	P@10	R@10	ILD	MIUF

KCB	0.289 (0.359)	0.150 (0.315)	0.221 (0.105)	1.053 (0.490)	0.397 (0.369)	0.115 (0.247)	0.188 (0.072)	1.038 (0.311)
RND	0.307 (0.335)	0.157 (0.312)	0.406 (0.174)	1.174 (0.404)	0.350 (0.336)	0.113 (0.248)	0.350 (0.130)	1.197 (0.385)
PPL	0.407 (0.407)	0.177 (0.310)	0.417 (0.164)	0.420 (0.243)	0.480 (0.402)	0.140 (0.249)	0.311 (0.136)	0.353 (0.135)

1. The best performing algorithms are bolded as determined via a 2-Way ANOVA and post-hoc Tukey HSD tests ($p < .05$). No interactions between week and algorithm were found. Full results of statistical testing are available in the repository¹.

2. Max R@10 as $M(SD)$: long courses - 0.351 (0.343), short courses - 0.303 (0.317) • Sample size: long courses - 825, short courses - 268.

mean and standard deviation of measures. The results were averaged over those of each student in each week.

5. RESULTS

Table 2 shows that both CSCLRec and CoPPR achieve high prediction accuracy, while maintaining acceptable diversity and novelty. They outperform their competitors according to precision for both 13-week and 6-week courses. Except for the very similar CoPPR algorithm, CSCLRec's precision is more than 18% higher than that of other recommenders. According to R@10, there is no measurable performance difference among the various algorithms. Considering the maximum possible recall is capped at 35.1% and 30.3%, CSCLRec's R@10 performance (21.9% and 18.8%) suggests it successfully identifies most of the relevant items.

In short courses, two of the best performers according to ILD are the unpersonalized baseline recommenders (RND and PPL) largely due to their introducing randomness. Apart from these random methods, those that emphasize interactions (i.e., MCF and PPR) had better diversity. As a tradeoff to accuracy, CSCLRec's diversity was acceptable - it was somewhere in the middle (3rd of 6 personalized recommenders in ILD) when baseline approaches (RND and PPL) are excluded because they have low precision.

As another tradeoff to high precision, novelty is not best achieved with CoPPR or CSCLRec. Content-based algorithms (i.e., KCB

and SCB) performed well from a novelty perspective as shown through their average MIUF scores. However, they had low diversity scores (ILD); they ranked last or second last.

To illustrate differences in performance over time, we use the LA course as an example (Figure 5). Note similar patterns were present in other courses and the change at week 10 coincides with the term break. In general, CSCLRec and CoPPR remained the best performing recommenders for precision throughout the semester.

Our proposed algorithm, CSCLRec, beats its competitors in precision from weeks 2 or 3 onwards (Figure 5). In contrast, when few inputs from students were available at the beginning of courses, the performance of content-based approaches was worse than the baselines. These results suggest the inclusion of socio-collaborative elements helps address the cold-start problem.

6. DISCUSSION

6.1 Recommender Algorithm Performance

The good performance of content-based recommender algorithms (CB) such as KCB and SCB in recommendation novelty highlights their ability to discover unpopular posts. It implies these approaches are better at helping students more quickly locate difficult-to-find but conceptually related discussions when the goal is to develop narrow but deep knowledge. This class of approaches may also increase forum equity by increasing the visibility of posts made by students with minority opinions that may otherwise go unnoticed in a popularity-based recommender scheme. However, CB algorithms' poor diversity performance suggests they suffer from the over-specialization problem because they only care about content similarity. This makes them unable to recommend semantically diverse resources. Since discussions on the same thread usually have similar content, the suggestions provided by CB recommendation algorithms are likely to direct users to a few specific threads, which may prevent exposure to new ideas. This goes against the general teaching goals of learning contexts where students are expected to discuss and debate different topics.

The family of collaborative filtering algorithms (CF), represented by MCF, showed relatively poor novelty when compared with the CB algorithms. This lack of novelty may discourage the participation of students who hold minority opinions, as has been seen in other investigations [64]. When comparing with PPR, CSCLRec's considerable enhancement in precision demonstrates the effectiveness of its three add-on modules. CoPPR also performs well, but its recommendation diversity appears to be lower. This finding indicates that the design of CSCLRec's content analyzer module benefits recommendation diversity as it is the only

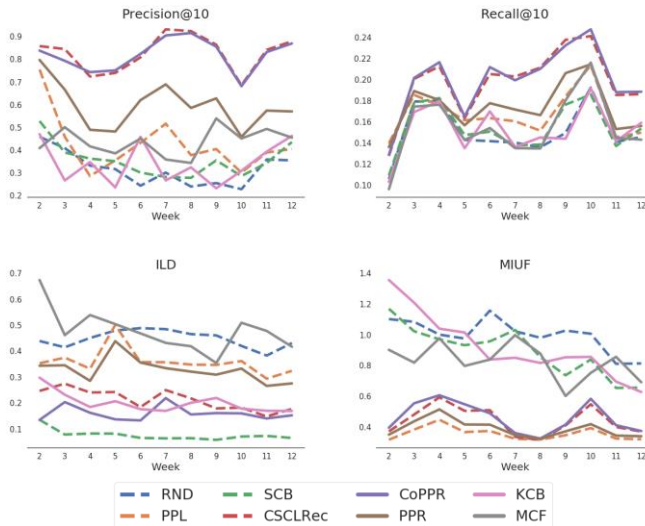

Figure 5. Weekly recommendation results for the LA course.

difference between CSCLRec and CoPPR. The outstanding performance of CSCLRec makes it the most appropriate choice to provide personalized suggestions in small-scale socio-collaborative learning contexts. However, we expect CoPPR to work better than CSCLRec in environments where the domain of discussion topics is narrower than those in our dataset as the use of hypernyms in CSCLRec is prone to mis-classification due to the granularity of the WordNet ontology. For example, in Chemistry, both “Sodium chloride” and “Copper(II) sulfate” are a “chemical compound”, but it makes little sense to link these two terms together as students might be talking about different things.

In contrast to traditional algorithms, CSCLRec and CoPPR integrate pedagogical considerations. The learner interaction profiler module is an obvious case. Unlike the one-size-fits-all recommendation strategy in other algorithms, it employs different strategies (i.e., adding more user-to-user edges) depending on learner type. Compared with the results of other approaches, the user-centered recommendation algorithm design of CSCLRec provided better prediction results by taking advantage of socio-collaborative learning principles.

While CSCLRec tended to perform well in recommendation accuracy, we should acknowledge that such support is not always what is needed for some learner types. For example, listeners not actively engaging in the discussions could be attributed to the recommendation lacking diversity. In this case, collaborative filtering approaches such as MCF might be a better choice. Moreover, new users may benefit from unpersonalized recommenders. For example, PPL could be used when we lack information about that learner because popular discussions may pique newcomer’s interest and encourage them to participate.

6.2 Recommender Support for Learning

The evaluations confirmed that our recommender system can forecast student behavior and give recommendations that match students’ preferences, as represented through their behaviors, in an e-learning discussion forum. Here we discuss the system’s potential to enhance students’ learning processes and outcomes in socio-collaborative learning spaces.

Rooted in learner interest, the generated recommendations can help reduce the time students spend searching for useful resources, thereby increasing the proportion of time dedicated to learning activities (i.e., discussing and sharing). The increased interaction should enable more knowledge-construction within the forum [37, 72], benefiting every learner with more opportunities to review and increase their understanding of the knowledge they have learned [85]. Many empirical studies have also found that student’s active participation in sharing can develop their critical thinking abilities [13] and benefit their overall course performance [19, 61, 84].

At the same time, pedagogical research shows that the diversity and novelty of ideas are critical to learning outcomes, especially during the process of knowledge co-construction. According to the theory of social constructivism, learner exposure to diverse perspectives can help them experience the types of cognitive conflict that lead to knowledge gain [32, 44]. Knowledge building principles also emphasize the importance of diversity and novelty of ideas to the knowledge scaffolding process [69]. Fortunately, CSCLRec’s novelty and diversity performance demonstrated the algorithm’s potential to support various collaborative learning activities in small discussion-based e-learning forums.

6.3 Potential Expansions

There are many ways to further improve the system’s performance when it is deployed online. First, real-time feedback from students can be collected and used to steer the strategies for the next round of recommendations. Second, the system could allow instructor and student configuration. This would allow users to refine the quality of recommendations and offer increased transparency to improve user satisfaction and trust in the recommendation mechanism [82]. In the future, we may adopt a human-in-the-loop approach and let course instructors adjust recommender parameters so they are more consistent with desired teaching plans.

More advanced NLP methods could also be used. For example, using knowledge graphs could benefit graph-based recommenders [56, 57, 59, 63]. Using such approaches could extend the semantic network in the content analyzer. Knowledge graphs relying on Linked Open Data usually have a wider coverage of entities which may allow them to overcome the current algorithms’ lack of phrases for representing key domain-specific concepts [74]. We had tried to use entity linking tools (e.g., DBpedia spotlight [22] and TagMe [31]), to query post content so that key phrases could be linked to entities in the knowledge base which would have replaced the hypernym portion of the PPR graph. However, their performance seemed poor in our context: many key phrases were not linked to the correct knowledge graph entities. The main reason may be that forum posts present disambiguation challenges to entity linking tools [36]. Moreover, some knowledge bases, such as DBpedia [6], have a limited number of verb entities because most verbs are treated as relations. Thus, building a knowledge graph specifically for an individual course seems to be the only realistic approach even though it would require considerable effort.

Lastly, while the proposed recommender performed relatively well, the ability of this recommender to support socio-collaborative learning processes within discussion forums still needs to be validated through in-vivo studies. Due to the limitations of using historical data, the present evaluation does not allow the direct observation of how learners will respond to the recommendations nor does it allow the measurement of the recommendations’ effect on learning processes [28, 30, 51].

7. CONCLUSIONS

In this paper, a novel recommendation approach that accounts for socio-collaborative learning principles in small discussion forums was proposed. This multi-relational graph-based recommendation scheme, CSCLRec, incorporates social network analysis, learner categorization, and natural language processing techniques. A similarly structured recommender, CoPPR, was also introduced for potential use in socio-collaborative learning contexts.

The performance of these proposed algorithms was evaluated in an offline experiment where they were compared against six other recommendation algorithms. The results from this evaluation show our approaches outperform others. Going beyond these measures, we discussed CSCLRec’s potential to help socio-collaborative learning processes, as well as its use cases and potential expansions from the perspective of a variety of measures (e.g., precision, diversity) and learning goals. As future work, we plan to deploy the system to examine its influence on student behaviors and learning.

ABSTRACT

We introduce DeepPerfEmb, or DPE, a new deep-learning model that captures dense representations of students' on-line behaviour and meta-data about students and educational content. The model uses these representations to predict student performance. We evaluate DPE on standard datasets from the literature, showing superior performance to the state-of-the-art systems in predicting whether or not students will answer a given question correctly. In particular, DPE is unaffected by the cold-start problem which arises when new students come to the system with little to no data available. We also show strong performance of the model when removing students' histories altogether, relying in part on contextual information about the questions. This strong performance without any information about the learners' histories demonstrates the high potential of using deep embedded representations of contextual information in educational data mining.

1. INTRODUCTION

The *testing* effect, the effect of including practice assessments as part of a students' learning phase, is known to have a strong positive influence on the knowledge acquisition process [2].

While the importance of regular practice and question answering is established, it is essential to balance it against the time constraints that students and instructors are facing [11]. The issue of having to teach and evaluate "*too much [...] in too short a time*" [10] is long-standing and leads to teachers having to make instructional choices with the information they have available [12]. It is thus important to identify factors that could help intelligent systems to ask the right question to the right students to maximise their knowledge gain in a limited time.

Extensive research has focused on building better student modeling to work towards this goal. Most of these approaches focus on extracting information from individuals'

histories of answers given, both right and wrong, to questions evaluating certain skills [4, 19, 18, 7]. Recent work has taken into account other factors, such as item-skills relationships, the relationship between a question and the skill it is meant to evaluate citedas3h, or individual item difficulty [17] in predicting student performance.

Deep knowledge tracing, which represents the state of the art in student performance, does not take into account the wealth of instance-specific interactions a student has with a given question, such as requesting assistance before attempting to answer it or the amount of time taken before answering.

We propose DeepPerfEmb, a deep learning model whose aim is to learn dense representations of this information and use it to improve the task of performance prediction. Our contribution is two-fold: we firstly argue that instance-specific information can be leveraged by such a model to reach a very high level of performance on predicting student correctness. We also introduce a variant of the model using exclusively contextual data, showing its ability to learn dense representations of these data points and perform strongly on the same task, despite having very limited information about the students' actions.

2. BACKGROUND

In the educational data mining field, there has been extensive research on attempting to model a learner's understanding of defined skills. Generally, this task is achieved through using observations related to a student's question-answering history. This information is used to estimate the student's mastery of the skills evaluated by the questions and is generally evaluated by using the model to predict whether or not they will answer a given question correctly. Such models are known as *Knowledge Tracing* (KT) models. *Bayesian Knowledge Tracing* (BKT), one of the most widespread classical method, models each students' knowledge as the latent variable of a Hidden Markov Model built using students' answering histories [4]. Such methods also rely on an evaluation of the probability of *slipping*, when a student answers incorrectly despite having mastered the skill, and *guessing*, when a correct answer is given without having mastered it.

More recently, many different approaches to knowledge tracing have been researched, mainly relying on extracting information from a vast amount of students' attempts at answering questions [7, 18]. Some of these models occasionally

Benjamin Clavié and Kobi Gal "Deep Embeddings of Contextual Assessment Data for Improving Performance Prediction" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 374 - 380

focus on or integrate other factors, such as modelling student forgetting [23] and estimated difficulty of question [15] or the possibility for a single question to relate to multiple, distinct types of knowledge [3]. These approaches often serve as the basis to intelligent learning schedulers, aiming to optimise the distribution of questions asked to students to maximise their knowledge gain [22, 25].

In recent years, deep learning has been utilised in order to produce better-performing variants of previous approaches. Notably, DeepIRT [27] and Deep Knowledge Tracing [19], have been introduced. These techniques, themselves a refinement on previous models, replace some of the prior building blocks with deep neural architectures while retaining the same foundational approach. Unlike more traditional methods, deep-learning based approaches rarely explicitly model the impact of forgetting, guessing or slipping, instead relying on the model to capture implicit information about these factors.

Online intelligent tutoring systems, such as the Assistment platform [20], have been invaluable in providing a large amount of data to train and evaluate such models. In addition to the information about students' attempts, failures and successes in answering questions, they generate a wealth of data about other aspects of the tutoring system. Notably, such systems may provide the user with the possibility of requesting assistance in answering the question, in the form of hints. It has been noted that such additional features are under-utilised in KT models and improve their performance when taken into account [26].

The focus of most of this prior work has been on exploiting the history of user answers, both right and wrong, in order to predict the likelihood that they have mastered a given skill. Such approaches reach a high level of performance and can accurately model the relationships between the skills evaluated [19, 16]. However, they encounter issues with students with relatively little or no interaction, and some of them exclude any student who has attempted to answer fewer than 10 questions [15, 3]. This issue is known as the *cold start problem*.

However, point-of-time snapshots of data contain a lot of additional information that has known little exploration. Such information, which we broadly refer to as **contextual information**, includes data directly related to the students' context, such as their school, the question they are solving, and the time it takes them to attempt to answer a question. We believe that such a method is complementary to approaches focusing on students' history in understanding the cognitive process of learning through assessment.

Prior work on deep neural networks has highlighted their ability to learn good embedding representations for discrete data [6]. This paper demonstrates that a modified version of this approach is able to outperform state-of-the-art KT model in the specific task of predicting student correctness. We show that our model learns a powerful representation of the data it receives as input, outperforming the state of the art, leading to a better understanding of how the questions asked to students can affect their performance.

3. PROPOSED METHOD

Our goal is to highlight how contextual data can be leveraged to improve question-correctness prediction. In order to do so, we use a deep learning model whose main purpose is to learn representations of this data in order to predict question-correctness. We then set out to leverage interpretation methods in order to understand which factors are considered important in making these predictions.

3.1 Data

We use two widely used public datasets made available by the Assistments online tutoring platform [20]: **ASSIST2009** [5] and **ASSISTChall** [1].

Each dataset is composed of hundreds of thousands of student interaction, with each interaction corresponding to a snapshot taken at the moment a student attempts to answer a question. Each snapshot contains a large amount of information, represented by multiple variables.

Two categories of data are present in each snapshot:

- **Meta-data, or contextual data:** Information about the overall context around the student and the question they are currently taking. Broadly, these are:
 - Information about the student's background (school ID, teacher ID...)
 - Information about the current question (problem set ID, question ID, skill evaluated ID, whether or not the question can be *scaffolded*...)
- **Current instance-specific data:** Information about the question the student is currently attempting. Broadly, these are:
 - Information about the student's help requests (hints requested, whether he has seen the final hint, where the questions stands in a *scaffolding*...)
 - Information about the time spent on the current question (time before first interaction, total time with question...)

Both datasets do not contain exactly the same information. ASSIST09 contains additional information in the form of both **interaction data**, such as time-to-first action and total time on question, and **contextual meta data**, notably relative to individual students' background, such as the specific assignment set they are working on or the ID of their class. Additionally, ASSISTChall is notable due to the presence of **scaffolded** questions. Scaffolding is an alternative to hints in making it simpler for a student to answer a harder question [21]. A scaffolded question is a question that can be decomposed into simpler questions (the *scaffolding questions*). The data contains variables describing the scaffolding status of an interaction: whether a question is the start of a scaffolding and whether it is part of one. For the purpose of our experiments, we consider scaffolding to be a type of contextual data as an attribute of the question being asked.

Due to the nature of the information contained in our snapshots, they contain both **categorical** and **continuous** variables:

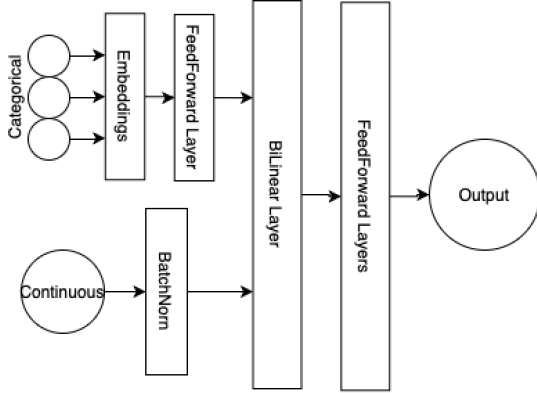

Figure 1: Simplified view of full model

Categorical variables, in this case, represent information that belongs to a finite number of defined categories, such as the skill being evaluated, the ID of the problem set the student is working through or the first action that they took on the current question (whether he requested a hint or attempted to answer it).

Continuous variables, on the other hand, represent information that can be measured, such as how long it takes for the user to first interact with the question after seeing it. For this work, ordinal variables, such as how many hints a student has received, are treated the same as continuous variables.

3.2 Preprocessing

We apply four major preprocessing steps to the data. For all of them except the removal of non-attempt snapshots, we use the data preprocessing utilities in the fastai2 library [8].

3.2.1 Removal of information leaks

Both datasets contain some variables that are perfectly correlated with student correctness. These are values such as the **hint** variable, which indicates that this interaction resulted in the user requesting a hint instead of trying to answer the question. The system will automatically label this interaction as "incorrect", although no attempt was made. As we do not want the model to learn incorrect information from this data and reach an artificially high score, these interactions are removed from the data.

Additionally, we also remove the variables that could lead to our model learning about an individual's student history. This includes the user ID, the total count of attempts by a user, the exact timestamp of interactions as well as additional information contained in ASSISTChall, such as a student's career path, final test score or emotional state.

3.2.2 Standardisation of Continuous Data

All the continuous variables are normalised before being fed to the model.

3.2.3 Handling Missing Continuous Value

Figure 2: Simplified view of meta-data only model

In some cases, all continuous variables are not available in a given snapshot. In order to account for this factor, we create a categorical variable corresponding to each continuous variable. This variable represents whether the information is present in the current snapshot or not. This allows the model to potentially capture the meaning of the absence of a given observation in a snapshot.

3.2.4 Pre-encoding of Categorical Data

Prior to being passed as input to the model, all categorical variables are ordinally encoded. This means that each possible value is replaced by an integer representing it. This step is crucial in ensuring the model can learn a dense representation of each possible value during training.

3.3 Model

Predicting the performance of a student based on a student's previous answers on questions meant to evaluate defined skills has been widely explored in work on *Knowledge Tracing*. Our aim is to build a model learning good representations of data without individual students' histories to predict whether or not a student will answer a question correctly.

Our model is a variant of the model presented in [6] with several modifications. The overall architecture can be described as follows.

3.3.1 Architecture

Structure

Embeddings: We create an embedding layer for each of the categorical variables we are processing. This embedding process uses a function e_i , which maps each possible categorical input x_i to a corresponding dense vector X_i :

$$e_i : x_i \mapsto X_i \quad (1)$$

This means that each of the categorical variables C will be mapped to a vector space. Each embedding is learned during the model training, and our aim is for the model to learn a representation of the categorical variables describing a given snapshot.

This step is the key step of our network, as the embeddings are trained alongside the full network during model training. With the task of predicting student correctness as its final objective, the model will use these embeddings layer to learn a representation for each of the variables it is given as an input.

Finally, the embedded representation of all the categorical variables are concatenated together into a single vector. This vector is then passed to a single feedforward layer, as defined below.

Bilinear Layer: The authors of [6] concatenated the normalised continuous inputs with the previously generated concatenation of the categorical variables. This approach resulted in unstable training and overfitting on ASSIST09. To alleviate this and allow our model to better weigh both types of features, we introduce a Bilinear layer.

The Bilinear layer takes two vectors as input, x and y , and turns them into a single output vector by multiplying them with a learned weight w and adding a learned bias b . The activation function and batch normalisation functions are both applied to this and every subsequent layers:

$$\text{BatchNorm}(\text{Mish}(x * w * y + b)) \quad (2)$$

FeedForward layers: The inputs are then passed through a classical feedforward architecture made up of linear layers which multiply the single input vector x by a learned weight w and add a learned bias b :

$$\text{BatchNorm}(\text{Mish}(x * w + b)) \quad (3)$$

Output layer: Our output layer is a normal feedforward layer with two output nodes, representing the prediction made by the model (correct or incorrect).

For the experiments exploiting both interaction and meta-data, we use the full version of our model as presented in Figure 1. When using only the meta-data, which is expressed through categorical variables exclusively, we do not need the weighing introduced by the Bilinear layer to allow the model to converge. As a result, in this situation, we use a simplified architecture presented in Figure 2.

Information

Activation: Our model uses the Mish activation function, which has been shown to consistently outperform common activation functions such as ReLU [14].

Batch Normalisation: It has previously been demonstrated that batch normalisation helps in both stabilising and speeding up the training of neural networks [9]. As such, we apply batch normalisation to our continuous input and to the output of every other layer.

Dropout: To prevent overfitting, which happens when the model learns too much about the training data and fails to generalise, dropout [24] is applied after every layer. We applied a dropout value of 0.4 during our experiments.

4. EXPERIMENTAL SETTING

We separate our experimentation into two parts. Firstly, we will use both of the data types we defined earlier, **meta-data** and **instance specific data**. This experiment will serve as a first indicator of our model’s ability to extract

information from the data and build efficient representation. We will then perform feature importance analysis on the models’ predictions to understand what variables have the strongest impact on its predictions.

Following this, we will attempt to predict question-correctness using exclusively **meta-data**. The aim of this experiment is to highlight how much the model can learn while using no information about the current assessment session or the learner’s history. We will then study the model to understand what representation of the data it has learned and how it impacts its performance.

We evaluate our model by performing 5-fold cross-validation and training the model for 100 epochs on each of the steps, saving and reporting the result obtained for the best epoch. For both datasets, we use the LAMB optimiser [29], which is better suited to large-batches training than other optimisers. In order to minimise training time, batch size is set to 24 000 and a maximum learning rate of 10^{-1} is used. In both models, we set the hidden dimensions of all layers to 100. These hyperparameters were obtained by a search using the first fold of the cross-validation set.

Due to the imbalanced distribution of our data, we report prediction results using the Area Under the receiver-operator Curve (**AUC**) metric, widely used in the literature for similar tasks [19, 3, 28].

For reference purposes, we have included results from the two most widespread implementations of Knowledge Tracing, BKT and DKT (here, DKT+ [28], a slight refinement of standard DKT) as well as from the current state-of-the-art, SAKT [16] in the comparison tables. For BKT, we use the best results reported in the paper introducing DKT [19]. Although the original data used by DPE and KT models is the same, we use different information found in the datasets. KT models use individual students’ interaction histories in order to predict performance and discard the rest of the information. On the other hand, DPE focuses on the contextual data and explicitly avoids the use of any student history data. As such, the scores are given in order to compare their results when focusing exclusively on the task of predicting question-correctness, but are not directly comparable as KT models leverage this task as a way to model student behaviour whereas our aim is to evaluate the importance of other, individual-unrelated features.

4.1 Using Instance Specific and Meta-Data

We first attempt to build a performance predictor using the two types of data we defined earlier, **contextual meta-data** and **instance specific data**. This model is likely to perform well, as it has access to a vast array of information about the current question as well as instance information such as the amount and type of help requested, the time before an action is taken as well as the total time spent on the current question.

4.2 Using Meta-Data

Our second experiment focuses on using exclusively the data we defined earlier as **meta-data**. This means that we remove interaction data from the input data.

Table 1: Results

Model	All-data		Meta-data	
	ASSIST2009 AUC	ASSISTChall AUC	ASSIST2009 AUC	ASSISTChall AUC
DPE (Ours)	0.87	0.76	0.75	0.63
BKT (reference)	0.69	N/A	0.69	N/A
DKT+ (reference)	0.82	0.73	0.82	0.73
SAKT (reference)	0.84	0.73	0.84	0.73

Figure 3: SHAP Values for ASSIST09 (all data)

Figure 4: SHAP Values for ASSISTChall (all data)

We do so in order to force the classifier to learn strong representations of contextual meta-data about the student and the question themselves. Reaching a good level of performance using such limited data would suggest that these representations could be exploited to discover new insights about assessment and be combined with traditional knowledge tracing techniques to develop better assignments.

4.3 Interpreting Results And Feature Importances

Following the evaluation of the classifiers, we will attempt to extract information about the factors that strongly influence our model.

We will interpret the model’s predictions using Deep Shapley Additive Explanations (DeepSHAP) [13]. By randomly replacing the values of subsets of the input features by uninformative values, DeepSHAP measures the influence of each input feature on different parts of a deep neural network and produces SHAP values for each prediction examples. SHAP values are an estimation of the importance of the feature in the prediction of each label made by the model.

We run DeepSHAP on randomly selected representative examples from the validation set and report the mean SHAP values of the features over all the examples, providing a visualisation of the features used by the model in its prediction. In all figures, class 0, the negative class, refers to a student answering a question incorrectly while class 1 refers to them having successfully answered the question. Although deep learning models remain black boxes and such interpretation techniques are vulnerable to adversarial examples, they provide a solid base towards making sense of model predictions.

5. RESULTS AND DISCUSSION

The results for this experiment are presented in Table 1, with BKT, DKT+ and SAKT results also presented for reference purposes.

When using all the available data, our approach performs extremely well in predicting question-correctness on ASSIST2009, reaching an AUC of 0.87 on ASSIST2009 and 0.76 on ASSISTChall, slightly outperforming state-of-the-art KT ap-

proaches for this task.

Our approach also reaches relatively high AUCs scores of 0.75 and 0.63 on ASSIST09 and ASSISTChall, respectively, when removing the instance-specific interaction data and using meta-data exclusively. This suggests that the models, while not outperforming student history-based methods, are able to extract enough information from contextual meta-data to reach a good level of performance, even outperforming the reported BKT results for ASSIST2009. In order to better understand what factors drive the models’ performance, we will compute the SHAP value corresponding to an estimate of the importance of each feature.

The SHAP values for the models exploiting the full data are presented in Figure 3 and 4. In ASSIST09, the temporal features, detailing how long the student has been interacting with the current question and how long until they first interact with the question, are of high importance.

More notably, on both datasets, the features that appear to be the most influential focus measuring the amount of help a student has needed to answer the current question. Features related to **hints**, such as the amount of hints requested for the current question (*hint_count* and *hint_total*), have a very strong influence on predictions. As hints are automatically given in case of failure, the hint-related features also capture information about the number of attempts made on the current question during the current question.

In ASSISTChall, features related to **scaffolding**, another form of assistance the student can receive, also have strong influence on the prediction, further supporting the importance of assistance factors.

The figure also shows that the other variables which we described as **meta-data**, such as the problem ID, do play a role predicting question-correctness, with a stronger impact on the likelihood of a question being answered incorrectly than correctly. We explore the influence of these factors further in Figure 5 and 6, showing SHAP values for the models which only use contextual meta-data.

In the case of ASSISTment, we notice that problems with the ability to end in auto-scaffolding are a strong predictor on whether or not a student will correctly answer a question.

Figure 5: SHAP values for ASSIST09 (meta-data)

This is on par with our previous results, having shown the importance of assistance in predicting correctness. A possible explanation to this high impact on prediction is that questions with built-in scaffolding are likely to be of a higher difficulty level, leading the instructor to include scaffolding questions. Likewise, *original*, indicating a question isn't part of a scaffolding, has a moderately strong impact.

Besides scaffolding, both models rely on contextual information about the questions, such as the ID of the problem set or the ID of the problem itself. In ASSIST09, the additional information about the students' background, represented by their class and teacher IDs, is shown to be important to the predictive ability of the model.

The strong results achieved by these models, with very little information about the user's studies and history of previous answers, highlight the value of the representations the model learned. Without relying on user-success history, this contextual meta-data only model is able to reach a high AUC score, even outperforming the classical BKT approach on ASSIST09. This further reinforces the potential of integrating novel techniques to leverage contextual information when evaluating student mastery rather than relying solely on students' answers history.

6. CONCLUSION AND FUTURE WORK

In this paper, we introduced a novel deep learning model able to efficiently learn deep representations of contextual assessment information.

We showed that the proposed model reaches a very high level of performance when using both meta and instance-specific data on predicting whether a student will correctly answer a question or not.

We further showed that we can reach a relatively high level of performance on the same task while using exclusively contextual meta-data and very limited student-related information.

Additionally, our analysis of the information learned by the model shows that there is valuable insight to be extracted from analysing its predictions.

This work highlights the potential of learning from contextual data on top of user-history data and could be extended in several ways.

Future work should focus on integrating such learned representations within traditional knowledge tracing systems and learning schedulers and comparing their predictions to those of DPE. Contextual information is complementary to the information these systems exploit and could lead to improvements in the learning process. We also intend to investigate how the results we have obtained could be used to enrich

Figure 6: SHAP values for ASSISTChall (meta-data)

theory-grounded models such as DeepIRT [27].

Furthermore, such an approach opens the way to extending current systems with additional external information, such as information about a user's interaction with course materials surrounding the knowledge evaluated.

ABSTRACT

Building and especially improving a classification kernel represents a challenging task. The works presented in this paper continue an already developed semi-supervised classification approach that aimed at labelling transcripts from educational videos. We questioned whether the size of the ground-truth data-set (Wikipedia articles) or the quality of the keywords used in the semi-supervised labelling have a significant impact on the accuracy metrics of the final obtained data model. Experimental results took into consideration three Wikipedia data-sets of *Small*, *Medium* and *Large* sizes. For each data-set there were used three sets of keywords: offered by video authors, determined by *rake-nltk* on available transcripts and determined by *rake-nltk* on Wikipedia articles that serve as training and testing data for the LDA model that determine keywords on the transcripts. Experiments show that the size of the data-set has little importance, while the quality of the keywords has a more significant impact. Therefore, an improved version of the previously developed classifier has been obtained by improving the quality of the keywords involved in semi-supervised training. This result paves the way towards further improvements that may finally be deployed as within a recommender system of educational videos at the Universitat Politècnica de València.

Keywords

classification, educational transcripts, keywords, data-set size

1. INTRODUCTION

Over the last few years, the quantity of online learning objects (LO) [6] and Massive Online Learning Courses (MOOCs) have increased dramatically representing a real boom in online learning. This boom of online learning resources has caused a problem for students, as they have hundreds of thousands of online documentation. At the same time, different approaches to discover topics and hidden semantic structures in text have been proposed with the goal of go

forward on topic modelling which has been a challenging and critical issue for information retrieval. Therefore, taking into account all of this, topic modelling has become in a trending topic for the e-learning research community. Following that trend, the *Universitat Politècnica de València* (UPV) in Spain launched a video lectures sharing website, called *Polimedia*¹, and a MOOC platform, called *UPV[X]*², which is powered by the edX MOOC platform³.

Both proposals have a basic search engine allowing students to search for videos (learning objects) by simply using a set of keywords. Current solutions compare these keywords with some typical metadata of the videos (title, authors, ...) and returns the set of videos that match with this data. Obviously, this basic retrieval solution overlooks any semantics, which produces incomplete results that do not take into account some videos that are relevant for the student but that do not include any of the keywords in their titles.

The MOOCs we are using in this work consists of a set of educational videos that have an automatic transcription of the lectures that is going to be used as part of the input data for this proposal. The motivation of this work is to use this information to help students to find more suited learning objects, personalized to their interests, in these massive online platforms where the number of learning objects grows quickly and they usually are not tagged correctly.

According to this, this paper focuses on the improvement of this search engine proposing a new retrieval method that uses a dataset extracted from Wikipedia articles and that is trained to classify keywords based on the topic of the available educational videos. This proposed model is an improvement of a previous work presented in [14], where pre-tagged wikipedia articles were used as ground-truth. In this work we improve this semi-supervised method by: 1) automatically tagging Wikipedia articles and using them to create an extended dataset for training the semi-supervised method, and 2) proposing an improved pipeline for cleaning the data, extract keywords and obtain a better classification model that improves the precision of the student's searches.

The rest of the paper is structured as follows: Section 2 presents some works related to the topic of this paper; Sec-

¹UPV Media, <https://media.upv.es>

³edX MOOC platform, <https://www.edx.org/>

tion 3 details the approach proposed by the authors; Section 4 presents some experimental results; and finally, Section 5 shows the conclusions of this work.

2. RELATED WORK

The problem of the correct keyword extraction is a recurrent problem over the last few years. Different works have appeared trying to solve this problem using different approaches. At the end, the idea is to have a solid set of words that concisely represent the content of a text (in this case the content of a learning object).

Most of the last approaches on document-oriented methods of keyword extraction use natural language processing (NLP) techniques mainly based on machine learning algorithms and statistical methods. One of the most well-known approaches is the work presented in [17] where authors propose the use of Support Vector Machines as a way to extract the most important keywords.

On the other hand, the work in [9] presents a solution based on the graph-based syntactic representation of text and web documents that combines supervised and unsupervised learning. In a similar way, the work presented in [7] proposes an unsupervised keyword extraction technique including several different ways of the conventional TF-IDF model with reasonable heuristics. Other approaches, like the work presented in [12] called Rapid Automatic Keyword Extraction (RAKE), employ unsupervised methods for extracting keywords which are domain-independent, and also, language-independent.

The latent Dirichlet allocation (LDA) model is one of the most used techniques to classify documents according to a set of topics. One example is the work presented in [1] that automatically captures the thematic patterns and identifies emerging topics using a non-Markov on-line LDA Gibbs sampler topic model. In the online educational field, the LDA model has been used in works such as the presented in [16] where the authors use topic detection for the analysis of the feedback submitted by students in online courses. The work in [10] tries to solve the problem of topic detection by identifying words that appear with high frequency in the topic and low frequency in other topics.

Some works face the keyword extraction problem in learning objects through the use of other approaches such as ontologies like the work presented in [8] that aims to improve the effectiveness of retrieval and accessibility of learning objects integrating semantic knowledge through domain-specific ontologies. In [4] authors use Wikipedia to associate learning objects to Wikipedia pages, specifically with the topics of those pages, trying to find relationships among learning objects.

Finally, recent work also uses intelligent algorithms and method to face other challenges of efficient videolectures management, such as video shots skimming [15] and supervised multi-class classification [5].

Opposite to most related works, our method is fully semi-supervised, with no need for a previously tagged database nor an ontology, that can act as ground truth to train the

models. Also, to the best of our knowledge, there are no other intelligent systems trained to automatically classify a Spanish database of educational videos.

3. PROPOSED APPROACH

From a classification perspective, the first issue is to clearly state the actual number of topics (i.e., labels) that exist in available transcripts. Since all transcripts come from educational videos from UPV, it certainly means that the number of topics is represented by the domains from which videos come from, that is *biology & sciences* (BS), *engineering* (E) and *humanities & arts* (HA). BS topic considers aspects of bacteria, diseases, bio-engineering, bio-medicine, E topic considers aspects of computers, electrical, architecture, civil, aerospace. In contrast, HA considers aspects of laws, arts, social and economic.

The proposed approach extends the semi-supervised method described in a previous paper-work[14]. It improves the data analysis pipeline in terms of accuracy of classification on the videos currently available in the database. As in the initial approach, the training on Wikipedia articles uses the SVM[3] classification algorithm, which used a Radial Basis Function (RBF) kernel from the *sklearn* library[11]. The validation approach uses the same two steps: 1) train on 70% of Wikipedia articles and cross-validate with 15%, 2) train on labelled transcripts and validate on remaining unseen 15% of Wikipedia articles.

Internally, the semi-supervised training has been performed on a set of labelled Wikipedia articles by building a data model that has been used for classifying educational transcripts and their associated keywords. The transcripts which had the same label as the keywords were considered correctly labelled and therefore were added to the initial training dataset. The newly obtained dataset is used in an iterative semi-supervised set up for training in an attempt to tag as many educational transcripts as possible.

One limitation of previous works is that HA items were mislabeled as E. This flaw may be caused by the fact that videos about HA reach more various subjects, that are not so domain-specific. Mathematics videos with proofs demonstration and analysis are also not correctly labelled as there is a large number of words that are not mathematics domain-specific. Many videos about the economy and economic environments tend to be categorised as E, as many explanations heavily use mathematics and calculus. A positive aspect is that the classification for BS items is acquiring excellent results, there are no confusions made for this domain. This behaviour is expected as this domain has many specific terms and principles, so videos from this area are easily classifiable and do not create confusions.

As a first step to improve the previous work[14] was to extend the Wikipedia articles data-set for training the semi-supervised method. This was done progressively, as we compared results with the previous ones and checked manually if the videos that were badly classified have been classified correctly. The decision about the amount and about which Wikipedia articles categories should be downloaded was made by manually analysing the clustering results from previous work. By doing so, we obtained best results with

three versions of datasets: a *Small* data-set (3747 Wikipedia articles), a *Medium* dataset (6373 Wikipedia articles) and a *Large* dataset (18527 Wikipedia articles).

Secondly, we focused on the importance of relevant keywords to obtain a good classification result. There were provided three sets of keywords supplied by three different methods. The first set was obtained using the same process from the previous paper[14] by using the keywords provided by the videos' authors. However, we observed inconsistencies as some videos do not offer keywords in their metadata. The second set of keywords was obtained by using *rake-nltk*[13] tool for extracting the keywords directly from the transcripts' text. Finally, the third set was obtained by using *rake-nltk* tool for getting keywords from the *Large* data-set of Wikipedia articles to use them as training and testing data for an LDA (Latent Dirichlet Allocation)[2] model that will extract domain-specific tags from the transcripts.

3.1 Training on more Wikipedia articles

Intuitively, more data should help to improve the accuracy, but in practical situation this may not happen. An issue that currently occurs in machine learning systems is whether or not the size of the data-set is too small for the classification problem. Proper debugging of the data analysis pipeline should clearly point out if current accuracy results may be improved by using a larger data-set or other leverages should be taken into consideration.

As a first approach, we tried to detect a pattern in the classification errors and download the appropriate Wikipedia articles to cover the subjects in the videos that were mistakenly classified. Consequently, when choosing the Wikipedia articles, not only the covering of the topics was taken into consideration but also the quantity of the articles about that subject was an important factor.

In response to this, additionally to the initial *Small* dataset used in the previous work[14] we obtained two new datasets: *Medium* dataset with a total of 6373 articles (i.e., 1219 BS articles, 2737 HA articles, and 1626 E articles), and a *Large* dataset with 18526 Wikipedia articles (including 5830 BS articles, 5882 E articles and 6814 HA articles).

3.2 Determining better keywords

The transcripts' keywords represent a key-point for the classification algorithm, as the quality of the classification may be directly influenced by the relevance and quality of the keywords.

A second solution was represented by the *rake-nltk* tool, as it supports the Spanish language and it provides good results for this language, too. *Rake-nltk* tool is a domain-independent keyword extraction algorithm which tries to determine key phrases in a body of text by analyzing the frequency of word appearance and its co-occurrence with other words in the text.

After trying to classify the videos in 3 clusters (BS, E and HA) using three different sized data-sets (i.e., *Small*, *Medium* and *Large*) for training and two different methods for assigning keywords to each transcript (the manually provided keywords by authors and the keywords extracted with *rake-*

nltk), we finally use the third method of providing more domain-specific keywords for every transcript: we used LDA as business logic for the implementation of transcript keywords recommendation system and used *rake-nltk* for providing keywords for Wikipedia articles to obtain training and testing data.

As the transcripts and the keywords from the metadata (i.e. authors' keywords) do not represent a valid data-set (the words used as keywords are either ambiguous, either too name specific and they often induce classification errors).

The limitation of the second method consists from the fact that the keywords provided by *rake-nltk* from transcripts were large and with numerous phrases without a focus on the essential subject of the video, also causing classification errors in some cases. So, a third solution was needed: there were used Wikipedia articles and keywords extracted with *rake-nltk* as training and testing data set for the LDA model to extract domain-specific keywords from the transcripts. The third solution is combining the *rake-nltk* tool with the LDA model. *Rake-nltk* will be used to extract keywords from the Wikipedia articles resulting in a labelled dataset that will serve later as training and testing dataset for the LDA model to extract domain-specific keywords from the transcripts.

The second approach provides new keywords for every transcript by using *rake-nltk*. The keywords extracted with this tool were also pre-processed by eliminating stop words and lowering all the letters. However, there still is one disadvantage for this method: the keywords extracted are large phrases that are not necessarily very domain-specific. Moreover, the extracted sentences are ambiguous in some cases, lacking the essential subject of the transcript. This error is most likely to be caused by the fact that the transcripts are not always subject-focused, they usually have an introduction about the teacher, the subject in general, many examples are provided. Hence, there is a broad set of words that may induce errors.

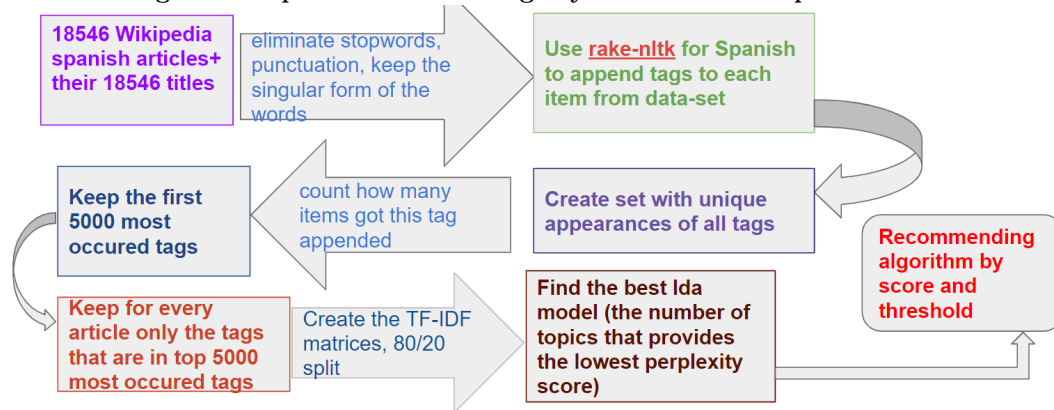

The third approach used *rake-nltk* tool, not for extracting keywords directly for our transcripts, but for extracting keywords for each article from the Wikipedia articles *Large* data-set (18526 articles). The tagged Wikipedia articles using *rake-nltk* will be used as training data for assigning keywords to the video transcripts employing LDA.

Figure 1 presents in detail the data analysis pipeline for the third method of providing keywords. This method is being described in this section in particular.

The following steps were followed for obtaining the domain-specific transcript tags recommendation algorithm utilizing LDA:

Create a balanced and large data-set of Wikipedia articles in Spanish. By saying to have a balanced data-set, there are supposed to be enough BS articles to obtain a set of keywords for BS, enough E articles to get a set of keywords for this domain, and most important enough HA articles to form a set of tags for this domain, too. The difficult part was to get a good set of keywords for HA domain, as this cluster covers a wide range of fields like Economy, Law,

Figure 1: Pipeline for extracting keywords from Wikipedia articles

Arts, Architecture, Language learning, Politics, Social Sciences, Philosophy, Psychology and basically anything that does not fit in the other two clusters.

Clean the text from the downloaded Wikipedia articles by lowering text, removing undesirable marks and stop words, using the singular form of the word. Append each Wikipedia article tags using *rake-nltk* tool and also *clean* (lower text, remove undesirable marks, remove stop words, use the singular form of the word) these tags. For better results, there are also tags extracted from the titles of the Wikipedia articles. That means that we pull tags for 18526 x 2 items.

Add all these tags in a set to have only unique appearances of the extracted tags.

Count how many Wikipedia articles were assigned to each tag from the set.

Get top 5000 most occurred tags (having less tags, it means that only the most occurred tags from each domain will be kept, and in this way, a classification with the semi-supervised method will be simpler to perform with a smaller training data-set)

Keep only the top 5000 occurring tags for each Wikipedia article.

Keep only the articles that are still labelled. After these operations, we end up with 21743 labelled items out of 37092 items.

Create the TF-IDF matrices by splitting our obtained data set in 80%/20%.

We try to **train various LDA models** using *sklearn*⁴ implementation [18], by assigning each of them a different topic number, then the different models are evaluated on the test set using the metric perplexity. By definition, the lower the perplexity, the better the model.

Showing the perplexity score for several LDA models with different values for *n_components* parameter, and printing the top words for the best LDA model (the one with the lowest perplexity).

Now that we have designed the workflow, we focus on the keywords recommendation algorithm for the transcripts, which is based on two main aspects:

- **Score** = probability that document is assigned to a specific topic, represents the topic's probability of generating the word.
- A word is considered as a relevant tag, when its score is superior to a defined threshold. After testing different values for the threshold, we decided to choose the threshold to 0.008, that is because, for this value, because with a threshold equals to 0.008 more than 95 percents of the transcripts have recommended tags.

Also, an advantage for obtaining keywords for every transcript employing *rake-nltk* combined with LDA would be that all the videos will be classified. In the original method, only the videos that were provided keywords by authors could have been taken into consideration. Now, as we offer keywords to every transcript, all the videos with an available transcript may be taken into consideration. An even bigger advantage is the fact that the training set contains articles about well-defined domains, their subject is focused on a small range of ideas, so the set of most frequently used tags will be very domain-specific, a fact that will be helpful for the classification algorithm.

4. EXPERIMENTAL RESULTS

After running the semi-supervised learning method for the *Small*, *Medium* and *Large* data-sets, and also with the three sets of keywords, the best results were obtained by training the semi-supervised method with the *Small* data-set of Wikipedia articles and the keywords provided employing *rake-nltk* for obtaining training and testing data and LDA to obtain the proper transcript's tags. The results are presented in Table 1. This table also provides a detailed insight of the semi-supervised training process results along with the number of transcripts added to the model in every iteration and with the classification accuracy obtained for each label. The computation of the classification accuracy metrics is done on the validation data-set, which contains only unseen data in the training step.

Analysis of the iterative semi-supervised training process in all nine scenarios (i.e., for three data-set sizes and for three methods of obtaining the keywords) revealed several pat-

Iteration (valid /available)	Accuracy	Class	Precision	Recall	F1-score
#1 (8487 / 14395)	0.92 (+/- 0.01)	Biology&Sciences	0.95	0.93	0.94
		Engineering	0.88	0.92	0.90
		Humanities&Arts	0.95	0.93	0.94
#2 (2375 / 5908)	0.96 (+/- 0.02)	Biology&Sciences	0.92	0.94	0.93
		Engineering	0.87	0.88	0.87
		Humanities&Arts	0.95	0.93	0.94
...
#8 (9 / 1940)	0.94 (+/- 0.05)	Biology&Sciences	0.90	0.94	0.92
		Engineering	0.85	0.86	0.85
		Humanities&Arts	0.93	0.90	0.92

Table 1: Validation scores for each iteration in the pipeline with the *Small* Wikipedia articles data-set and the keywords provided by means of *rake-nltk* for obtaining training and testing data and LDA to obtain the proper transcript’s tags.

terns. The first observation regards the fact that the number of iterations has low variance. So, irrespective of the size of Wikipedia data-set and the method for obtaining the keywords the number of iterations is in the range from six to twelve. This observation represents a clear indication that the size of the training data-set of Wikipedia articles does not highly influence the semi-supervised learning. Another observation is that each step in the semi-supervised training keeps unchanged or slightly decreases the F1 score, while slightly increasing the accuracy of the 10-fold cross-validation on the Wikipedia test data-set. This observation shows that all experiments are consistent and produce similar behavioural patterns in terms of accuracy, precision, recall and F1-score measures evolution in terms of evolution during semi-supervised training.

Table 2 presents the validation scores for all the three data-sets (i.e., *Small*, *Medium* and *Large*) and all three keywords data-sets.

The first observation regarding the validation results from table 2 regards the fact that there are no big differences in terms of overall accuracy and F1-scores for the three data-sets of keywords and for each training data-set. Still, the method with *rake-nltk* for Wikipedia articles keywords and LDA for obtaining transcript keywords generally has better scores than the other two methods for cluster 2. Still, it has usually lower scores for cluster 1. This pattern shows an indication that improvements in classification metrics should focus on classes where poorly results occur.

We further observe that scores tend to slightly decrease as the data-set is getting larger. Therefore for the *Medium* data-set, only the method with *rake-nltk* for extracting transcript keywords provides better results than it does with the *Small* data-set. A particular result consists in major score decreases for cluster 1 for the *Medium* data-set. This is mainly due to the unbalance of this data-set regarding the items from labelled in class 1. The imbalance of class 1 is also signalled by the excellent results for classes 0 and 1 in the experiment with *Large* data-set and the method with *rake-nltk* for Wikipedia articles keywords and LDA for transcript keywords.

Despite the *Large* data-set used for training the model, comparing the time required to train the model with the *Small*

data-set and the time necessary to train the model with the *Large* data-set with all three sets of keywords, we have noticed that the time has doubled in the worst case, even though the data-set used is 6 times larger than the initial one.

Besides, the method to obtain keywords employing *rake-nltk* and LDA transcript keywords provide a better running-time execution for the *Small* and *Large* data-sets than the original keywords set as the number of iterations is also smaller.

The method with *rake-nltk* and LDA transcript keywords provides best result for the *Small* data-set, though the *rake-nltk* transcript keywords methods has the best results for the *Medium* and *Large* data-sets. For the method to obtain domain-specific keywords for transcripts employing *rake-nltk* to extract Wikipedia articles keywords and LDA to extract the proper keywords for transcripts, the tags distribution per the 10 topics of the model is presented in Table 3. We also notice that the 10 topics do not mix the three domains that we are interested about: E tags are found only in topics that do not contain tags from the other two domains, and the same for BS tags and HA tags. There can be easily noticed the domain that each topic covers: the topics with indexes 1, 2, 5, 9 and 10 are focused on HA domain, the topics with indexes 4, 6 and 8 are focused on E domain, and finally, the topics 3 and 7 are focused on BS domain.

Furthermore, the topic order shows that the first three most important topics are 4, 3 and 9, where 4 is focused on the E domain, 3 is concentrated in BS tags, and 9 is focused on HA tags. Considering that the first three most important topics contain one topic for each of the three domains that we are interested in, ultimately confirms that the model is suitable for our purpose. In addition, the following 3 topics in the topic order are also distributed equally across the three domains.

We can notice that the original keywords provided by authors are provided in different styles: some of them are too specific(tool names that are not so common), some of them too ambiguous to be categorised to a domain, and some of them provide domain-specific terms, but those terms may not be so standard in that domain in such a way to be correctly categorised by put semi-supervised method that is not trained on a massive data-set.

Table 2: Validation scores for all data-sets and keywords sets

Data-set	Keywords	Accuracy/Avg F1	Class	Precision	Recall	F1-score
Small	Original keywords	0.94/0.88	0	0.96	0.86	0.91
			1	0.84	0.86	0.85
			2	0.86	0.90	0.88

T 8	ecuación / ingeniería / inteligencia / artificial
T 9	política / análisis / marketing / rama / arteria
T 10	industrial / industria / plano / internacional
Order	[4, 3, 9, 8, 7, 5, 10, 6, 2, 1]

The third method, the one that uses *rake-nltk* for providing keywords to the Wikipedia articles used for training and LDA for extracting transcript tags, provides a few labels, but they are very domain-specific. The tags that can be resulted from this method come from a relatively small set of possible tags (this set is formed by the most commonly used terms in the 3 domains of our clusters), so the most relevant tags from this set will be chosen.

This is an advantage for our semi-supervised method as we can provide good results with a relatively small data-set for training. The words used for tags by this method are very likely to be well categorised by the semi-supervised method as they are very common only in the are of one of the three domains.

5. CONCLUSIONS

This paper has presented a method which combines the extraction of keywords from a Wikipedia data-set with the automatic classification of learning objects using LDA to obtain better keywords for searching educational videos. This will allow students to find more accurate resources for videos that have not been appropriately tagged by authors.

Using Wikipedia for creating a labelled data-set has allowed us to build a balanced set of articles that have been used to train a model for extracting keywords from educational video transcripts. However, in future works, it would be interesting to provide an automatic mechanism for building balanced training data-sets.

The proposed has been tested using a real environment, concretely the video lectures sharing website of the *Universitat Politècnica de València*, which has more than 55.000 short videos mainly in Spanish. Results have shown the benefits of this proposal for classifying learning objects into categories (specifically Biology&Sciences, Engineering and Humanities&Arts), which will help students in their search of appropriated learning resources.

Future works should focus on improving accuracy of the classification especially for the classes with poorer results, that is *Engineering* and *Humanities & arts* as *Biology* transcripts are correctly classified. The obtained classifier may be further used for labeling new videos that may be added into UPV Media site.

ABSTRACT

Intelligent tutoring systems for programming education can support students by providing personalized feedback when a student is stuck in a coding task. We study the problem of designing a *hint policy* to provide a next-step hint to students from their current partial solution, e.g., which line of code should be edited next. The state of the art techniques for designing a hint policy use supervised learning approach, however, require access to historical student data containing trajectories of partial solutions written when solving the task successfully. These techniques are limited in applicability when needed to provide feedback for a new task without any available data, or to a new student whose trajectory of partial solutions is very different from that seen in historical data. To this end, we tackle the *zero-shot* challenge of learning a hint policy to be able to assist the very first student who is solving a task, without relying on any data. We propose a novel *reinforcement learning* (RL) framework to solve the challenge by leveraging recent advancements in RL-based neural *program synthesis*. Our framework is modular and amenable to several extensions, such as designing appropriate reward functions for adding a desired feature in the type of provided hints and allowing to incorporate student data from the same or related tasks to further boost the performance of the hint policy. We demonstrate the effectiveness of our RL-based hint policy on a publicly available dataset from Code.org, the world's largest programming education platform.

1. INTRODUCTION

In recent years, there has been an increasing focus on developing educational tools for STEM (science, technology, engineering, and mathematics) and computing. Problem-solving skill, i.e., ability to solve multi-step problems by deductive reasoning, is one of the key ingredient of learning in these domains [14, 25]. For instance, while working on a coding task, a student iteratively writes, tests and refines the code to arrive at the final solution [8, 23, 27, 24].

One of the difficulties in designing assistive algorithms for these open-ended coding tasks is that the state space, i.e., the set of partial solutions that students might arrive at when solving the task, is *unbounded*. For instance, for a simple coding task from the *Hour of Code* (HOC) challenge by Code.org [5], the correct solution contains only 5 blocks (see Figure 1), whereas students can create millions of unique partial solutions in the process of solving the task [23]. When solving such tasks, it is evident that students can get stuck at a state (i.e., a partial solution) and do not know how to proceed (i.e., which action/edit to apply). Intelligent tutoring systems empowered by machine learning techniques held a great promise in supporting such stuck students by providing personalized feedback, e.g., explaining misconceptions and giving guidance on what to do next [31, 16, 2, 24].

We focus on the well-studied feedback mechanism in programming education called *next-step* hints: When a student is stuck at a given state, the system suggests the next edit that student should make to their current code to proceed [3, 8, 16, 23, 27, 20]. In the context of block-based languages that are extremely popular in educational tools for visual programming [21, 5, 24], the suggested hints correspond to one of the allowed actions from the student's current code (e.g., adding or removing a block, and changing a conditional in one of the blocks), see Figure 1. Inspired by the work of [3, 23, 20], we refer to the function that provides such hints to the student from any partial solution as *hint policy*.

The key challenge in designing a hint policy is that the space of partial solutions is unbounded even for simple coding tasks and there is a huge variability in students' trajectories of partial solutions [23, 20, 34]. A number of techniques proposed in the literature use a graph representation of the task (with nodes denoting partial solutions and edges denoting single edits that convert one partial solution to another) [3, 9, 23, 35, 27]. These techniques then use historical student data and domain knowledge to capture the editing behavior of capable students (or experts) on this graph. However, these techniques face serious scaling issues as the problem size grows and are only applicable in settings where we have access to large volume of historic data for the task.

In recent years, new techniques have been developed using a supervised learning approach. These techniques leverage code embeddings to compactly represent the space of partial solutions and can provide hints to students with trajectories that have never been observed in the historical data [22, 20].

Aleksandr Efremov, Ahana Ghosh and Adish Singla "Zero-shot Learning of Hint Policy via Reinforcement Learning and Program Synthesis" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 388 - 394

Figure 1: Illustration of next-step hints feedback by our hint policy. (a) shows the HOC-18 task from the *Hour of Code* (HOC) challenge by Code.org [5]. A student solves the task by starting from empty code and builds up the solution using blocks available in the visual interface, also see [23]. (b) shows the correct solution—this is the code that solves the task with minimal number of 5 blocks. (c) shows the current partial solution of a student who is solving this task. (d.left) shows the next-step hint by our hint policy that will be provided as feedback to the student. (d.right) shows the subsequent next-step hint by the policy if student were to ask another hint after receiving the first hint.

In particular, the state of the art technique by [20], *Continuous Hint Factory* (CHF), learns a *regression function* as the hint policy which can identify the most likely hint as a vector in an embedding space and then translates this vector back into a human-readable edit. In comparison to techniques using graph representations, CHF is more scalable and requires access to fewer samples of student data (just enough to learn the generic editing behavior of capable students or experts for the task).

While these state of the art supervised learning techniques are less data-hungry and computationally more powerful, they are still limited in applicability when needed to provide feedback for a new task without any available data, or to a new student whose trajectory of partial solutions is very different from that seen in historical data. Especially with intelligent tutoring systems having the ability to generate tasks on the fly [28, 1, 12], the problem of providing feedback to the very first student on a task is increasingly important. In this paper, we tackle the following *zero-shot* learning challenge: *Can we design a hint policy for a task to provide hints to the very first student solving the task?*

1.1 Our Approach and Contributions

Our approach towards zero-shot learning of hint policy is based on the *reinforcement learning* (RL) framework. In the RL terminology, the set of all possible partial solutions corresponds to the state space, the possible edits from a partial solution defines the state-dependent actions and transition dynamics, and reaching the correct solution quickly yields higher reward (we refer the reader to [26, 29] for a background on RL). Our framework is inspired by recent works [4, 11] that have shown that deep-RL techniques applied to neural embeddings of the code are effective in learning policies to synthesize new programs and to do program repair even if no/minimal training data is available for the task. Intuitively, the problem of providing a hint from a current partial solution is equivalent to one-step of synthesizing the program from this partial solution [17, 10]. However, we note that learning hint policy using RL poses its own practical challenges because the policy needs to provide hints from *any* partial solution which could be arbitrarily bad—this is in contrast to program synthesis and program repair where the initial starting states for RL are limited to either an empty code [4] or a set of partial solutions which are close to the correct solution [11], respectively. The idea of using RL for designing hint policy is also inspired by the seminal

work on *Hint Factory* [3]; however, unlike [3] which relies on historical student data and uses the graph representation of partial solutions, our RL framework uses code embedding and a neural network policy for efficient training.

One might ask what are the advantages of using RL compared to supervised learning techniques for zero-shot challenge. First and foremost, RL enables an effective self-exploration of the solution space by leveraging reward signals (such as receiving higher rewards when a policy can synthesize the correct solution in a fewer steps or can reduce compiler errors). Furthermore, the RL framework is amenable to several extensions for boosting the performance. For instance, if additional student data is available from the same or related tasks, it is possible to bootstrap by combining techniques from imitation learning within RL framework [19, 11]. Also, we can easily incorporate additional human knowledge or features into the policy by designing appropriate reward functions [4, 11]. In summary, this power and flexibility of the RL framework makes it especially suitable for zero-shot learning as it gives us the following ingredients: (i) automatically exploring the solution space or generating synthetic training data [32, 11, 34], (ii) incorporating any available data or expert knowledge to bootstrap and boost the performance [15, 34], and (iii) transferring knowledge from one task to another [18, 6, 7]. Below, we summarize our main contributions:

- We introduce the zero-shot challenge for learning a hint policy to provide next-step hints to the very first student working on a coding task.
- We propose RL framework for zero-shot learning of hint policy. Our framework leverages the representation power of code embedding and a neural network policy for efficiently learning to provide hints. The framework is amenable to several important extensions, e.g., bootstrapping via additional data if available.
- We evaluate the performance of our RL-based hint policy on a publicly available dataset from Code.org, the world’s largest programming education platform [5, 23]. We show significant improvements in next-step hint accuracy w.r.t. the state of the art supervised learning technique.

2. PROBLEM FORMULATION

In this section, we formalize the problem of learning next-step hint policy for programming education.

2.1 Coding Task, Partial Solutions, and Edits

We define the problem in the context of a fixed coding task (e.g., HOC-18 task as shown in Figure 1a). We assume that the correct solution for the task is known. For brevity of presentation, we consider that the correct solution is unique (in fact, the uniqueness holds for HOC-18 task, see Figure 1b). We denote all possible partial solutions for the task by the set S . Note that S is a countable, infinite set. A partial solution $s \in S$ is a piece of code, e.g., as shown in Figure 1, and we denote the correct solution by $s^* \in S$. For any $s \in S$, we define the set of edits that can be applied to s by the action set A_s . In block-based languages, the set A_s corresponds to adding or removing a block in s , editing a conditional for one of the blocks in s , or moving blocks within s . For a partial solution $s \in S$ and an edit $a \in A_s$, the next partial solution obtained by applying a to s is denoted as $s \oplus a$.

2.2 Hint Policy for Next-step Edits

When a student attempts the task, they generate a trajectory of partial solutions denoted as $\xi = (s_0, s_1, s_2, \dots, s_k)$ where k is the trajectory length. Here, s_0 is the empty code, and s_k is the student's latest/current partial solution. Upon reaching s_k , the student might be stuck and is unable to decide how to proceed. Our goal is to help this student by providing feedback as the next-step hint $a \in A_{s_k}$ in the form of an edit that allows the student to make progress. Figure 1c shows one such partial solution s_k and Figure 1d (left) shows the next-step hint that could be provided.

Formally, the next-step hint policy $\pi(\cdot | \xi)$ provides a probability distribution with support over actions A_{s_k} where s_k is the last partial solution in the trajectory ξ . Note that when a policy depends on the whole trajectory ξ , then it can infer the knowledge of the student based on this trajectory and can provide personalized hints. However, the existing hint policy techniques discussed in Section 1 consider myopic policies. A myopic policy $\pi(\cdot | s_k)$ provides a probability distribution with support over actions A_{s_k} and takes as argument only the last partial solution s_k (i.e., ignoring the trajectory of how student reached s_k). In our work, we also focus on learning such a myopic hint policy.

2.3 Evaluation Criteria

As an evaluation criterion, we use the standard approach in literature (e.g., see [23, 20]) where the performance of a hint policy is measured in terms of prediction accuracy. We assume access to a set of expert annotations given by $D_{\text{hints}} = \{(s_i, N(s_i))\}_{i=1,2,\dots,n}$: here, for a partial solution $s_i \in S$, the experts have annotated that the next partial solution where a student should transition to should be among the set $N(s_i) \subseteq S$. In our experiments, we will use the publicly available annotation dataset from [23] for evaluating hint policy on HOC tasks. For a policy π , we use the following notion of *unweighted* prediction accuracy:

$$\frac{1}{n} \sum_{i=1}^n \left(\sum_{a \in A_{s_i}} \pi(a | s_i) \cdot \mathbb{1}(s_i \oplus a \in N(s_i)) \right) \quad (1)$$

where $\mathbb{1}(\cdot)$ represents an indicator function (cf. [23] which uses a notion of accuracy *weighted* by frequency). Note that, this measure of prediction accuracy does not capture the long-term pedagogical value of providing hints to students, and we further discuss this as future work in Section 5.

3. LEARNING HINT POLICY USING RL

In this section, we present our approach to zero-shot learning of hint policy via reinforcement learning (RL) framework.

3.1 RL Framework

3.1.1 Hint policy learning environment as an MDP

In reinforcement learning, a learning algorithm (agent) interacts with an environment typically modelled as a Markov Decision Process (MDP). Here, we present the MDP corresponding to the problem of learning hint policy. We define the MDP $M = (S, A, P, R, S_0)$ as follows:

- S corresponds to the set of partial solutions;
- $A = \cup_{s \in S} A_s$ is the set of all possible actions, and A_s is the set of actions or edits possible in state s ;
- $P : S \times A \times S \rightarrow \mathbb{R}$ denotes the transition dynamics. $P(s' | s, a)$ is defined only for $a \in A_s$. We have $P(s' | s, a) = 1$ for $s' = s \oplus a$, and 0 otherwise.
- $R : S \times A \rightarrow \mathbb{R}$ denotes the reward function. $R(s, a)$ is defined only for $a \in A_s$. A simple reward function could be to set a small negative reward for every action taken and a high reward for reaching the correct solution termed as “goal” (i.e., when $s \oplus a = s^*$). We will discuss more about designing rewards in Section 3.3.
- $S_0 \subseteq S$ is the set of initial states. This corresponds to the states which would be used to initialize an episode when training the hint policy. One way to pick set S_0 is to randomly sample states from S , limited to some upper limit on the code size.

We consider an episodic, finite horizon learning setting [29, 26]: A learning episode starts with an initial state s_0 sampled at random from the set S_0 , then the agent interacts with the environment over discrete time steps t , and the episode ends when one of the following happens: (i) either the agent reaches goal state s^* , or the episode length exceeds a pre-specified threshold (set to 20 in our experiments).

3.1.2 Policy gradient methods

While a variety of RL algorithms can be used to learn a policy, we consider policy gradient methods which have proven to be highly effective for dealing with large-scale problems [29, 11, 4]. These methods learn a parametrized policy $\pi_\theta(a | s)$ where θ represents the parameters; then, a gradient ascent method is employed to update parameters that would increase the expected reward of the policy in the MDP. In our work, we use a neural network to learn the policy, i.e., θ represents the weights of the network. Given a state s and action a , the policy network parametrized by θ outputs a score $H_\theta(a | s)$. Using these scores, we define the policy by the following softmax distribution: $\pi_\theta(a | s) = \frac{\exp^{H_\theta(a | s)}}{\sum_{a' \in A_s} \exp^{H_\theta(a' | s)}}$.

We use the classic REINFORCE policy gradient method (see [29, 33]) to update the weights of the network. In an episode, the RL agent performs an update as follows. First, an initial state s_0 is sampled, and then the policy π_θ is executed until the episode ends, thereby generating a sequence of experience given by $(s_t, a_t, r_t)_{t=0,1,2,\dots,L}$ where L represents the episode length. Then, in this episode, for each

Figure 2: Number of states (i.e., unique partial solutions) grows exponentially w.r.t. the size (i.e., number of code blocks).

(a) Code embedding using tree-structured LSTM

(b) Neural architecture of our hint policy

$t \in [0, L]$, we use the following gradient update with η as learning rate:

$$\theta \leftarrow \theta + \eta \cdot \underbrace{\left(\sum_{\tau=t}^L r_\tau \right) \cdot \left(\nabla_\theta \log(\pi_\theta(a_t | s_t)) \right)}_{\text{gradient at time step } t \text{ in an episode}} \quad (2)$$

This gradient update can be computed efficiently for our setting—we refer the reader to [33, 29] for detailed discussion. We provide the implementation details in Section 4.2.

3.2 Efficient Learning of Hint Policy

3.2.1 Dealing with infinite state space

Figure 2 shows the number of states (unique partial solutions) w.r.t. the size (number of blocks) of a partial solution. Here, for reference, we also show number of states for a more complex language Karel [21]. Note that even if the correct solution is of small size (e.g., 5 for HOC-18 and HOC-4 tasks), the struggling students end up writing large partial solutions even up to 50 blocks length [23]. To deal with this computational challenge of a very large state space, we rely on code embeddings to have a featurized state representation. In our work, we train code embedding inspired by recent developments in using structured RNNs for embeddings, in particular Tree-RNN model by [22] used for HCO-18 embeddings and Tree-LSTM model by [30]. We represent the code as an Abstract Syntax Tree (AST) as shown in Figure 3a, and then this tree structure is used to process the blocks. When training, we require syntactic edit distance between raw states to be preserved after the embedding. In Section 4.2, we provide a more detailed description of the process used to learn the code embedding.

3.2.2 Dealing with state-dependant action sets

In a typical RL setting, the action set A is finite, and the standard architecture for training the network is to have $\phi(s)$ as input and the scores $H_\theta(a | s) \forall a \in A$ as output (i.e., output layer has $\mathbb{R}^{|A|}$ size). In our setting, the action set A is infinite, and the allowable actions from a state s given by set A_s are state-dependant. To tackle this challenge, we use the neural architecture as illustrated in Figure 3b. We train a network which takes as input both $\phi(s)$ and $\phi(s \oplus a)$. To evaluate the probability of taking action a from state s , we first compute scores $H_\theta(a' | s)$ for all $a' \in A_s$, and then probability of action $\pi_\theta(a | s)$ is given by the softmax distribution.

3.3 Incorporating Additional Knowledge

3.3.1 Designing rewards

We can easily incorporate additional human knowledge or features into the policy by designing appropriate reward functions [4, 11]. For instance, by changing the reward values $R(s, a)$ based on the type of action a (e.g., deleting an existing block vs. adding a new block), we can train a hint policy that favours certain types of hints. One can further incorporate more complex criterion such as suggesting hints at the last line in the code to capture students' current focus of attention which is important for better interpretability of hints [20]. Reward design also allows us to incorporate intermediate partial solutions that serve as milestones toward the final correct solution. By providing positive rewards for such states representing milestones, our hint policy would automatically learn to steer the students towards such states. Furthermore, this approach can also help in speeding-up the learning process of the RL algorithm by dealing with sparse reward problem (see Section 4.2 on how we use this idea to speed up the learning).

3.3.2 Bootstrapping from data when available

While we introduced RL framework to tackle the zero-shot challenge, the proposed framework allows one to bootstrap from additional student data if available from the same or related tasks. In fact, the existing RL-based techniques used in program synthesis and repair (see [4, 11]) have shown that substantial performance gain and convergence speed-up can be obtained by bootstrapping from available data.

We incorporate student data to bootstrap RL-based hint policy as follows. Consider we have access to a set of trajectories of successful students or experts who solved the task, given by $\Xi = \{\xi_j\}_{j=1,2,\dots}$. From these trajectories, we can obtain dataset of edits made by successful students, represented as $D_{\text{train}} = \{(s_i, s_i \oplus a_i)\}_{i=1,2,\dots}$. The RL policy network can be bootstrapped by additionally training from D_{train} using cross-entropy loss. The gradient update is given below where η' represents the learning rate:

$$\theta \leftarrow \theta + \eta' \cdot \underbrace{\left(\sum_{(s, s \oplus a) \in D_{\text{train}}} \nabla_\theta \log(\pi_\theta(a | s)) \right)}_{\text{gradient for cross-entropy loss}} \quad (3)$$

Further implementation details are provided in Section 4.2.

4. EXPERIMENTAL EVALUATION

In this section, we evaluate the performance of our RL-based hint policy on a publicly available dataset from Code.org [5].

4.1 Hour of Code Tasks

We consider HOC-18 and HOC-4 tasks from the *Hour of Code* (HOC) challenge by Code.org, the world’s largest programming education platform [5, 23]. HOC-18 task, shown in Figure 1, is an advanced task in HOC challenge with 7 different types of blocks (“move forward”, “turn left”, “turn right”, “repeat until”, and “IF ELSE” with three different types of conditionals). HOC-4 is a simpler task with only 3 types of blocks (“move forward”, “turn left”, “turn right”). For the zero-shot setting, we do not require availability of any student data for comparing different hint-policy techniques (see Figures 4a and 4c for $x = 0$ on the x-axis). Beyond zero-shot setting, we also evaluate the performance when additional data becomes available (see Figures 4a and 4c for $x = 9, 12, 15$ on the x-axis). For these experiments, we use the trajectories of successful students from the dataset provided by [5, 23]. We refer the reader to [5, 23] for further details about these tasks and the available dataset.

4.2 Implementation Details

Here, we briefly provide implementation details for the following: (i) code embedding, (ii) RL-based hint policy, and (iii) three baselines. Some details are omitted because of lack of space—the source code would be made publicly available with the final version of the paper for reproducibility.

4.2.1 Code embedding

We learn a separate embedding for HOC-18 and HOC-4 tasks, and the code embedding is learnt prior to training the hint policy. We begin by sampling 400 random states limited to a size up to 6 blocks, and then use pairwise syntactic edit-distance between these states to generate a training dataset containing triplets of the form $(s, s', d_{\text{synt}}(s, s'))$: here $d_{\text{synt}}(s, s')$ represents the syntactic edit-distance between s and s' in terms of the number of edits required to convert s to s' . Given these triplets, we train a neural embedding $\phi(\cdot)$ so the $\|\phi(s) - \phi(s')\|_2 \approx d_{\text{synt}}(s, s')$. As shown in Figure 3a, we use the Abstract Syntax Tree (AST) representation of a state s which is then traversed in a preorder depth-first way to produce a sequence of blocks. The resulting sequence is passed through bi-directional LSTM where each unique block of the HOC language is encoded differently (cf., Tree-RNN model of [22] and Tree-LSTM model of [30]). The size of the feature representation used for our experiments is given by $\dim_\phi = 40$, i.e., $\phi(s) \in R^{40}$.

4.2.2 RL-based hint policy

For the policy network, we use a 5-layer fully connected neural network with the following architecture: (i) the input layer has $2 \times \dim_\phi$ units for $\phi(s)$ and $\phi(s \oplus a)$; (ii) the first three hidden layers have 128 hidden units and the fourth hidden layer has \dim_ϕ hidden units; and (iii) the output layer linearly aggregates \dim_ϕ values from the last hidden layer to produce the score $H(a | s)$. All hidden units use ReLU activations with a dropout rate of 0.1, and we use ADAM optimizer for training [13]. The policy actions are taken using a softmax distribution as discussed in Section 3. Below, we discuss the rewards and stopping criteria used for train-

ing, separately for zero-shot setting and when bootstrapping from available student data:

- *Zero-shot learning setting:* We set reward $R(s, a)$ as +100 when $s \oplus a = s^*$, and -1 otherwise. The training is done until the average reward of the policy is saturated. To further speed up the convergence, we use intermediate rewards in the training process by adding an additional term of $-d_{\text{synt}}(s \oplus a, s^*)$ to the reward. Here, d_{synt} represents the syntactic edit-distance between two states (same function as used in generating training data for code embedding). These intermediate rewards during the training process allowed us to speed up the convergence by order of magnitude, without effecting the overall performance of the trained policy. After this speed up, the number of episodes required until convergence varied from 5000 to 20,000.
- *Additional student data is available:* We first pre-train the network using cross-entropy loss with the data sampled from D_{train} . This pre-training is done for 20 epochs where each epoch consists of multiple gradient updates as follows: A batch of data is sampled from D_{train} of size given by $\text{batchsz} = 32$ and a gradient update is performed using this batch as per Eq. 3; this process is repeated $\frac{|D_{\text{train}}|}{\text{batchsz}}$ within an epoch. After this pre-training phase, we train the policy network using rewards for 2000 episodes using the gradient updates in Eq. 2. Given that the pre-training phase already provides a good initialization of the policy network, we used modified reward signals in this case as compared to the zero-shot setting: (i) we set reward of +20 for reaching the goal instead of +100 and (ii) we reduced the value of intermediate rewards and set it to $-0.05 \cdot d_{\text{synt}}(s \oplus a, s^*)$ by scaling it down.

4.2.3 Baselines

We compare our RL-based hint policy REINFORCE-HP w.r.t. several baselines as discussed below. In particular, we consider baseline techniques which can be implemented efficiently, without requiring any explicit graph representation of the state space which is computationally intractable (also, see Figure 2).

As a simple benchmark, we use RANDOM-HP: a baseline policy that simply selects an action $a \in A_s$ randomly when providing a hint for state s . As another natural baseline, we consider FREQNEXT-HP which uses historical student data as follows. Based on the available data, a frequency count $\text{count}(s, a)$ is maintained for each (s, a) pair counting the number of times action a was taken from state s by students in the historical data. Then, when providing hint for a state s , the hint is chosen from a distribution given by the following softmax distribution: $P(a|s) = \frac{\exp(1 + \text{count}(s, a))}{\sum_{a' \in A_s} \exp(1 + \text{count}(s, a'))}$.

Next we discuss a baseline based on the state of the art technique of *Continuous Hint Factory* (CHF) [20] that uses supervised learning approach. We adapt the key ideas of CHF to our setting and refer to the resulting hint policy as REGRESSION-HP—this adaption allows us to directly compare REINFORCE-HP with REGRESSION-HP as both these hint policies use the same embedding and same historical data when available. Below, we discuss three key steps required in training REGRESSION-HP:

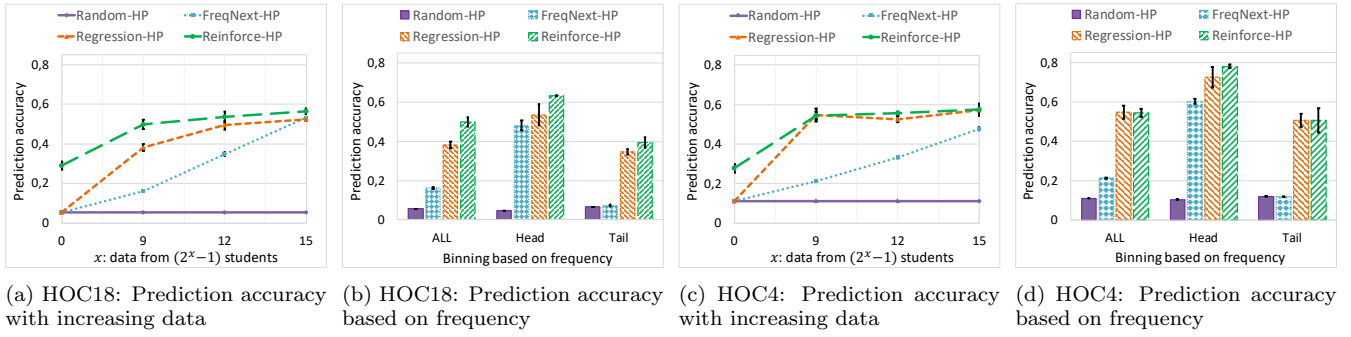

Figure 4: **(a)** shows prediction accuracy for HOC-18 task. $x = 0$ on the x-axis corresponds to the zero-shot setting. REINFORCE-HP achieves over 20% absolute improvement in the prediction accuracy compared to baselines. **(b)** shows results for HOC-18 task when states are binned into “Head” and “Tail” based on frequency counts, and a moderate amount of historical student data is available (see details in Section 4.3). REINFORCE-HP performance on low-frequency states is even higher than the overall performance of any of the baselines. **(c, d)** shows the results for simpler task of HOC-4.

- *Embedding* (cf. Section 3.1 of [20]): For REGRESSION-HP, we use the same code embedding as used for REINFORCE-HP. Our code embedding is similar to the Euclidean embedding space used by [20] which was obtained by preserving syntactic distances between raw states.
- *Regression function* (cf. Section 3.2 of [20]): Then, we learn a regression function in the embedding space which can identify the most likely hint as a vector in this space. This step makes use of available student data D_{train} as discussed in Section 3.3, and learns a function f_{reg} that can map $\phi(s)$ to $\phi(s \oplus a)$ for $(s, s \oplus a) \in D_{\text{train}}$. We use neural network to learn this function f_{reg} , in contrast, [20] used Gaussian process regression. We use a 4-layer neural network to learn f_{reg} with essentially the same architecture as the one used to learn REINFORCE-HP, except that (i) the input layer has \dim_{ϕ} units for $\phi(s)$, (ii) the output layer here has \dim_{ϕ} units to produce $\phi(s \oplus a)$ (this corresponds to what was the last hidden layer in REINFORCE-HP neural architecture).
- *Human-readable hint* (cf. Section 3.3 of [20]): Finally, when providing hint for a state s , we first compute the hint in embedding space as $f_{\text{reg}}(\phi(s))$ and then convert this to an editable hint $a \in A_s$ as the one that minimizes $\|f_{\text{reg}}(\phi(s)) - \phi(s \oplus a)\|_2$.

4.3 Results

Figure 4 shows the results for HOC-18 and HOC-4 tasks, averaged over 3 runs of all the hint policies. Figures 4a and 4c show the overall average prediction accuracy. The $x = 0$ point in these plots corresponds to the zero-shot setting and measures the prediction accuracy of next-step hint for the very first student who is attempting the task. For both HOC-18 and HOC-4 tasks, our RL-based policy REINFORCE-HP has a significant improvement over baselines by about 20% gain in absolute accuracy. For the HOC-18 task, even when a moderate amount of data becomes available (e.g., see $x = 9$ on the plot which is equivalent to data of 511 students), REINFORCE-HP improves w.r.t. REGRESSION-HP by 10% gain in absolute accuracy.

In Figures 4b and 4d, we further analyze the performance of different hint policies when training using a moderate amount of available data (corresponding to $x = 9$ in Fig-

ures 4a and 4c which is equivalent to data of 511 students). In these plots, states are binned into “Head” and “Tail” based on frequency counts as available in the dataset obtained from [23]. Here, the bin “Head” corresponds to top 40 states and “Tail” corresponds to bottom 40 states based on frequency. For HOC-18 task, REINFORCE-HP performance on low frequency states is even higher than the overall performance of any of the baselines: this highlights the power of RL framework that allows an efficient self-exploration of the solution space when learning the hint policy. These plots also illustrate that techniques such as FREQNEXT-HP that rely on frequency counts can have much worse performance on the tail segment of states compared to head segment of states.

In summary, these results demonstrate that the proposed RL framework enables us to learn an effective hint policy in the zero-shot setting, and the performance can be further improved with the availability of student data.

5. CONCLUSIONS AND FUTURE WORK

We tackled the challenge of zero-shot learning of hint policy to be able to provide hints for the very first student working on a coding task. Building on the recent advances in RL-based neural program synthesis, we proposed an RL framework for learning hint policy. Using a publicly available dataset from Code.org, we showed that our policy achieves significant improvements over state of the art supervised learning techniques when no or very limited data is available. Furthermore, the results demonstrated that our proposed framework is easily amendable, e.g., it can benefit from historical student data to further boost the performance.

There are several research directions for future work. As an evaluation criterion, we used the prediction accuracy of next-step hints based on expert annotations. In future work, it would be important to do user studies and understand the pedagogical value of these hints. In this work, our hint policy provided hints based on only the current partial solution of the student. It would be important to learn a richer hint policy that can provide personalized hints by accounting for the whole trajectory of the student. Finally, it would be interesting to apply our framework to more complex learning scenarios (e.g., with more complex coding tasks or with a more complex language involving additional concepts such as the ability to declare variables).

ABSTRACT

Reading to learn is a quintessentially self-regulated activity. In order to provide effective support for this activity it is necessary for us to understand how students adapt their self-regulation behaviors within disciplinary reading environments. In this paper, we utilize student response data from a digital literacy platform to examine the association of students' behaviors with the difficulty of questions embedded in science texts. We analyzed 131 distinct physical science questions used in 641 middle school classes within *Actively Learn*, a digital reading platform. We investigated the association of question difficulty and students' behaviors, including reading, annotating, highlighting, and vocabulary lookups. Our findings show that students found multiple choice questions with multiple correct answers hard to answer and exhibited more reading behaviors when attempting them. Short answer questions appeared to be easier; students engaged in more annotation, highlighting vocabulary lookups when attempting easy short-answer questions compared to difficult multiple-choice questions.

Keywords

Question Difficulty, Student Behavior, Self-Regulated Learning

1. INTRODUCTION

Reading to learn, as students do when engaging with disciplinary texts [35], is a quintessentially self-regulated activity [26]. When presented with a block of text, students can approach it by reading end to end, make notes as they go or not. They can also skip around for clues, or even explore in larger chunks. How they choose to do so will be driven by their own study habits [38], as well as the context of the assignment itself.

Students who are trying to answer a set of questions typically read differently than students who are trying to master general material [11,18]. As the questions change, so will their behavior. They will, to paraphrase Karl Llewellyn, *read with new eyes* [23]. In order to effectively support students in reading to learn, it is necessary to understand how students adapt their reading and learning strategies when faced with problems at different perceived levels of difficulty and of different types. Understanding these changes will allow us to model their behaviors, identify successful and unsuccessful approaches, and provide effective interventions as necessary.

Prior researchers have shown that reading scientific texts requires both reading strategies and self-regulated learning (SRL) strategies [14, 25, 47]. As Butler and Cartier emphasized, understanding SRL requires understanding students' learning contexts [9]. The context of learning is nested: geographical, socio-economical, within-school, and within-classroom. At the classroom level, students' engagement in learning is shaped by teacher's instructional approaches and by interactions with the teacher and peers [9].

Our goal in this study is to examine how students may perceive question difficulty at the *class-level*, and how students vary their individual reading and self-regulated learning activities in response to it. The context of our study is *Actively Learn* (AL) [1], an online reading platform that is used in schools in the United States. For this study, we focus on readings and test items in middle school science domains. We answer the following research questions:

RQ 1. How does students' performance vary with question difficulty?

RQ 2. What SRL strategies do students use before and after each question ?

2a. How did SRL strategies vary with question difficulty?

2b. How did reading vary with question difficulty?

We collected log data from 11,832 middle school physical science students within the AL platform. We extracted reading, annotating, highlighting, and vocabulary lookup events from the log traces and we estimated the difficulty level of questions by class level. We compared our difficulty level with a comparable analysis from item response theory (IRT) [18]. And we

Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 395 - 402

evaluated students' reading and SRL strategy usage with question difficulty.

2. LITERATURE REVIEW

Our research draws on prior work in two primary areas: research on self-regulated learning activities in reading-to-learn situations and research on question difficulty analysis from student performance data.

2.1 SRL and Science Achievement

SRL, as described by Zimmerman, involves four regulatory components during learning: goal setting, self-monitoring, self-evaluating, and using strategies to control progress toward a goal [51]. Learners who are more capable at self-regulation tend to set more challenging goals for their academic achievement than those who are less capable [53]. They use self-monitoring strategies to monitor their time on task and to solve conceptual problems [8]. Self-evaluation, in this context, means being able to judge the outcomes of self-monitoring processes [52]. In the process of self-evaluation, a student changes learning strategies to achieve their learning goals [53]. Prior researchers have provided a range of SRL models, these include Pintrich's SRL framework [31], Zimmerman's cyclic phases model [50] and Winne and Hadwin's model [46]. While they rely on different assumptions, all of them frame learning as an active process wherein learners set goals by understanding topics or domains, regulate their cognition processes, and modify behaviors to achieve goals in light of self-evaluation [47, 31].

SRL strategies are linked to subject domains [48]. Researchers have examined SRL strategy usage and academic performance in science in game-based learning [37, 40], classroom settings [4], and in agent-based learning environments [7]. Francois et al. examined students' SRL usage strategies in an agent-based learning environment for human biology, MetaTutor [7]. They found high performing students both took more notes and made more summaries. Low performing students, by contrast, struggled to find relevant pages to attain their subgoals within the system. Andrzejewski et al. examined an SRL intervention in a 9th grade earth science class [4]. They found SRL intervention strategies had different effects on students with different socioeconomic status. Students from minority groups (non-white or economically disadvantaged) benefited more than those in the majority group (white and middle class). Rutherford examined the role of SRL within a curriculum integrated mathematics game, ST Math, and found that differences in students' SRL monitoring was related to their academic performance [37].

Our goal in this analysis is to evaluate students' SRL usage in middle school science reading. Our work is situated in the interactions between SRL monitoring and control—as students engage with text and with embedded questions, they assess the difficulty of the task they encounter and adjust their behaviors accordingly. We operationalize the SRL activities related to reading strategies students would use during the control phase of SRL as annotating [24], highlighting [45], and vocabulary lookups, as we believe that these features serve as proxies for SRL behaviors, and we have studied their relation to question type in a prior publication [16]. Science texts involve key concept words and vocabulary terms. Students' reading comprehension and motivation has been found to decrease due to introduction of concept words [22]. Vocabulary lookups can help students to understand concepts when they first encounter

them. Annotation requires that students comprehend text and frame it in their own words [24]. Highlighting texts involve SRL activities through the use of monitoring information and connecting that information to prior knowledge [45].

2.2 Question Difficulty from Student Data

Understanding the difficulty level of test items has a wide range of applications in educational data mining (EDM); this includes work on the optimal arrangement of curricula [21] and on the design of adaptive tests or personalized learning environments and intelligent tutoring systems (ITS) [30]. Item difficulty can be assessed based upon the design of a question and its classroom context [20], or it can be evaluated empirically based on observed student performance in real contexts [28]. This empirical approach is particularly important for the development of practical adaptive learning and tutorial environments. Although the structure of a question specifies the knowledge required, the *operational difficulty* of a task, that is the difficulty for a given student, is dependent upon the class context, the amount of individual preparation or scaffolding provided, the students' skill level, and whether they are working on it individually, as part of a team, or as a whole class.

Consequently, a number of prior EDM researchers have developed a number of domain and student models which can be used to identify structural relationships between tasks and to assess their difficulty based upon empirical performance. These efforts include: work on q-matrices that map items to required skills and levels (e.g., [5]); learning factors analysis and other student performance models such as Bayesian Knowledge Tracing (BKT) (e.g., [10, 13]); and item response theory (IRT) [19]. Item Response Theory (IRT) is regarded as the “gold standard” of estimating question difficulties from student response data. The simplest version of IRT is the “Rasch Model” [32], which associates a skill or ability to each student and a difficulty level to each question.

Different intelligent tutoring systems (ITS) [44] and other learning environments have utilized student-system interaction logs to estimate question difficulty empirically. Pardos and Heffernan for example, extended the BKT model to handle item difficulty in a mathematics tutoring system, ASSISTment [30]. QuizGuide, an assessment system for Java programming [39], predicts subjective difficulty on questions from predefined weights and student performance. The predefined weights were assigned by domain experts. ELM-ART II, a web based Lisp programming tool [40], uses fixed difficulty and weight for each item. A student's knowledge level is updated based on correct or incorrect attempts on each item and difficulty level. Researchers have further utilized student attempts coupled with IRT to estimate question difficulty [33]. Fouh et al., for example, utilized the total number of attempts and guessing behavior to understand difficult topics in a Data Structure course [17]. Additionally, they compared their approach to IRT.

As in this prior work, we focus on using student-system interaction logs to estimate the operational difficulty of our questions; however, as we are particularly interested in variation across instructors, we analyze our data at the class level.

3. DATASET

In this section we describe the Actively Learn platform [1] and our dataset construction process.

3.1 The Actively Learn (AL) Platform

AL is a digital literacy platform aimed at students in primary and secondary (K-12) education. AL is designed to improve students' reading proficiency. The platform allows teachers to assign reading texts as assignments to class with embedded questions, which may include optional automated feedback. Assignments in the AL platform can range from one page to multiple pages. Questions in AL can be multiple choice (MCQ) and short answer (SA), including free texts and fill in the blanks. Teachers may use predefined reading texts and questions available within AL or introduce their own as assignments. MCQs are automatically graded, whereas SAs are not. AL questions are graded on a scale of zero to four. Figure 1 shows a reading text in the AL interface.

Physical science reading texts in the AL platform are organized following the Next Generation Science Standards (NGSS) guidelines [2]. The NGSS for middle school physical science (PS) has four standards: (i) PS1: Matter and its Interactions, (ii) PS2: Motion and Stability: Forces and Interactions, (iii) PS3: Energy, and (iv) PS4: Waves and their Applications in Technologies for Information Transfer. Students are expected to analyze and interpret data (PS1 standard), plan and carry out investigations (PS2 standard), develop and use models, analyze data (PS3 standard), and use mathematical thinking and demonstrate understanding (PS4 standard) [2].

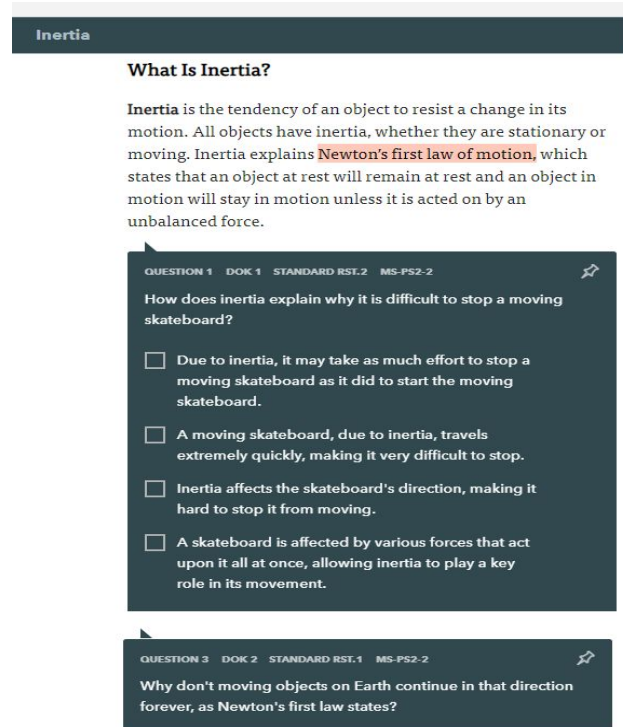

Figure 1. A reading text and embedded questions. Question 1 is an MCQ and question 3 is a SA.

AL's developers state that the platform provides opportunities for teachers and students to deeply engage with text [34].

Students can highlight, annotate, and look up unknown words as they proceed through the readings.

3.2 Dataset Construction

Our current study focuses on middle school science reading assignments in the AL platform. Our dataset includes records of students who completed assignments in 2018. Our dataset includes 17,886 student records across 1,033 classes. After plotting histograms of class sizes, we excluded classes with fewer than 10 or more than 60 students. This left us with 83.45% of students. We also excluded any student enrolled in multiple classes, as we believed these accounts could be for testing purposes. After selecting classes, we filtered the dataset by questions. We selected 131 predefined AL questions used in at least two classes. The final resulting dataset has 11,832 students and 913 assignments used in 641 classes. We extracted students reading, highlighting, annotating, and vocabulary lookup events from log data trace.

4. METHODOLOGY and RESULTS

In this section we describe our methodology to answer our RQs.

4.1 RQ1: How does students' performance vary with question difficulty?

In our study, a question can be used by different classes. As we do not have access to student demographics and other confounding variables, we opted to aggregate difficulty data at the level of classes. Additionally, we compared our approach with the IRT model. Note that estimating question difficulty is not the goal of our study. We aimed to investigate how students' reading and SRL strategy usage varies with question difficulty. In order to analyze how students respond to different questions, it is necessary to identify suitable metrics to assess question difficulty. First we defined metrics to assess each question difficulty within a class from student interaction data. We analyzed how a question's perceived difficulty varies across classes using our defined metrics. We assessed students' performance on questions categorized by question difficulty. Next, we performed IRT analysis to examine the relationship between question difficulty and student performance. We compared findings between two approaches.

4.1.1 Question Difficulty and Student Performance: Student Interaction Data

We analyzed the students' performance on each question to assess the difficulty of the question. To calculate a student's performance, we took the ratio of max score achieved to number of attempts on a question. Questions in AL are graded on a scale [0-4]. For our assessment, we normalized the students' scores to a range of [0-1]. We defined the performance of a student i on a question q as

$$r_i = \frac{\text{scaled maximum score on } q}{\text{no. of attempts on } q} = \frac{\text{maximum score on } q/4}{\text{no. of attempts on } q} \quad (1)$$

Equation (1) computes a student's score of a question on a scale of zero to one, one representing good performance and zero representing poor performance.

We computed difficulty level (dl) of a question q as

$$dl = 1 - \frac{\sum_{i=1}^n r_i}{n} \quad (2)$$

where n is the number of students in a class who attempted q , and r is the students' performance on q as defined above. A $dl \sim 0$ value indicates an easy question and $dl \sim 1$ indicates a difficult one.

To analyze the difficulty of a question q across classes, we computed difficulty ratio of q across classes as follows:

$$\text{Difficulty ratio of question } q = \frac{\text{No. of classes with } dl \geq 0.5 \text{ for } q}{\text{No. of classes used } q \text{ in assignments}} \quad (3)$$

We plotted histograms of difficulty ratio for 131 questions. After examining the histograms, we observed more questions with difficulty ratio < 0.2 and fewer questions with difficulty ratio > 0.5 . We grouped questions into three categories by their difficulty ratio as shown in Table 1.

We plotted histograms of student performance on each question, r , for three categories of questions. Figure 2 presents the histograms (next page).

4.1.2 Question Difficulty and Student Performance: IRT Analysis

The IRT method estimates the probability of a student getting an item correct based upon the item difficulty and the students' ability. We applied the 1-parameter logistic IRT model (1PL) model, also known as the Rasch model. The 1PL model describes test items considering only one parameter, *item difficulty*, b . The 1PL model is a logistic curve, i.e., it evaluates how high the latent ability level needs to be in order to get a 50% chance of getting the item right. Item difficulty is estimated from the student responses.

Table 1: Question category by difficulty ratio (diff. ratio)

Question Category	MCQ	SA	Total
<i>Easy</i> (diff. ratio < 0.4)	6	75	81
<i>Medium</i> ($0.4 \leq \text{diff. ratio} \leq 0.6$)	5	26	31
<i>Hard</i> (diff. ratio > 0.6)	11	8	19

The Rasch model assumes a boolean score for each student response to questions. To apply the 1PL model, we need to map students' responses to 0 or 1 computed from equation (1). We assigned zero if $r < 0.5$ and 1 otherwise. We fit the 1PL model to 131 questions using the 'ltm' package in R [36].

We plotted per-item characteristic curves (ICC) from the fitted model. The X axis of the ICC represents students' latent ability and the Y axis represents the probability of answering the question correctly. The range of the X axis is $[-4, 4]$, where zero indicates *average* ability. We plotted ICC curves for *Easy*, *Medium*, and *Hard* questions separately. We also plotted item information curves (IIC) from the fitted model. The IIC curves shows how much information about students' ability an item provides. A difficult item will provide little information about a

student with low ability and vice versa for easy items. We plotted IIC curves for *Easy*, *Medium*, and *Hard* questions separately.

4.1.3 Results for RQ1

From the student interaction results shown in Figure 2. We also notice the number of students receiving zero in *Easy* questions is higher than *Medium* and *Hard* ones.

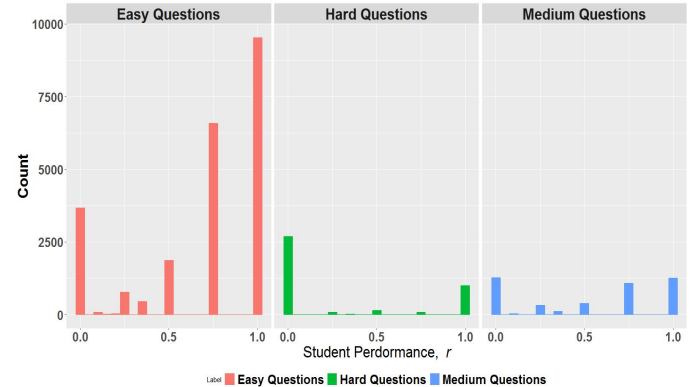

Figure 2. Student performance by question difficulty

In Figure 3 (next page) we show our ICC results for *Easy*, *Medium*, and *Hard* questions. Each line represents the ICC curve of one question. We observe that the ICC curves for *Easy* questions are mostly on the left side of zero, indicating *Easy* questions required lower ability for correct attempts. Comparing ICC curves of *Easy* and *Hard* questions, we note that *Hard* questions have curves more on the right side of the X axis. The probability of answering a *Hard* question correctly decreases as curves go from left to right.

The IIC curve shows how much information about students' ability a question gives. From Figure 3, we observe *Easy* questions curves provide information about students with average and below average abilities (the peak of curves are mostly on the left side of $X = 0$. $X = 0$ refers to average ability). Similarly, IIC curves for *Hard* questions provide information about high ability (the peak of curves are mostly on the right side of $X = 0$) levels.

4.2 What SRL Strategies Do Students Use Before and After Questions?

In this section we present our methodology and results for RQ2. We calculated SRLs at student-level to understand how students' SRLs varied by question difficulty.

4.2.1 Methodology for RQ2

To investigate the association between students' reading and SRL behavior with question difficulty, first we need to identify student sessions. The AL system does not record student sessions. Therefore, we relied on a data-driven approach to identify sessions as described by Kovanovic et al. [41] and Adithya et al. [3]. AL records timestamps of students' question submission, reading, annotating, highlighting, and vocabulary lookup behaviors. We aggregated timestamps of students' actions into a unified log. We plotted histograms of time intervals between consecutive actions to identify outliers and estimate the last action of any time period [41].

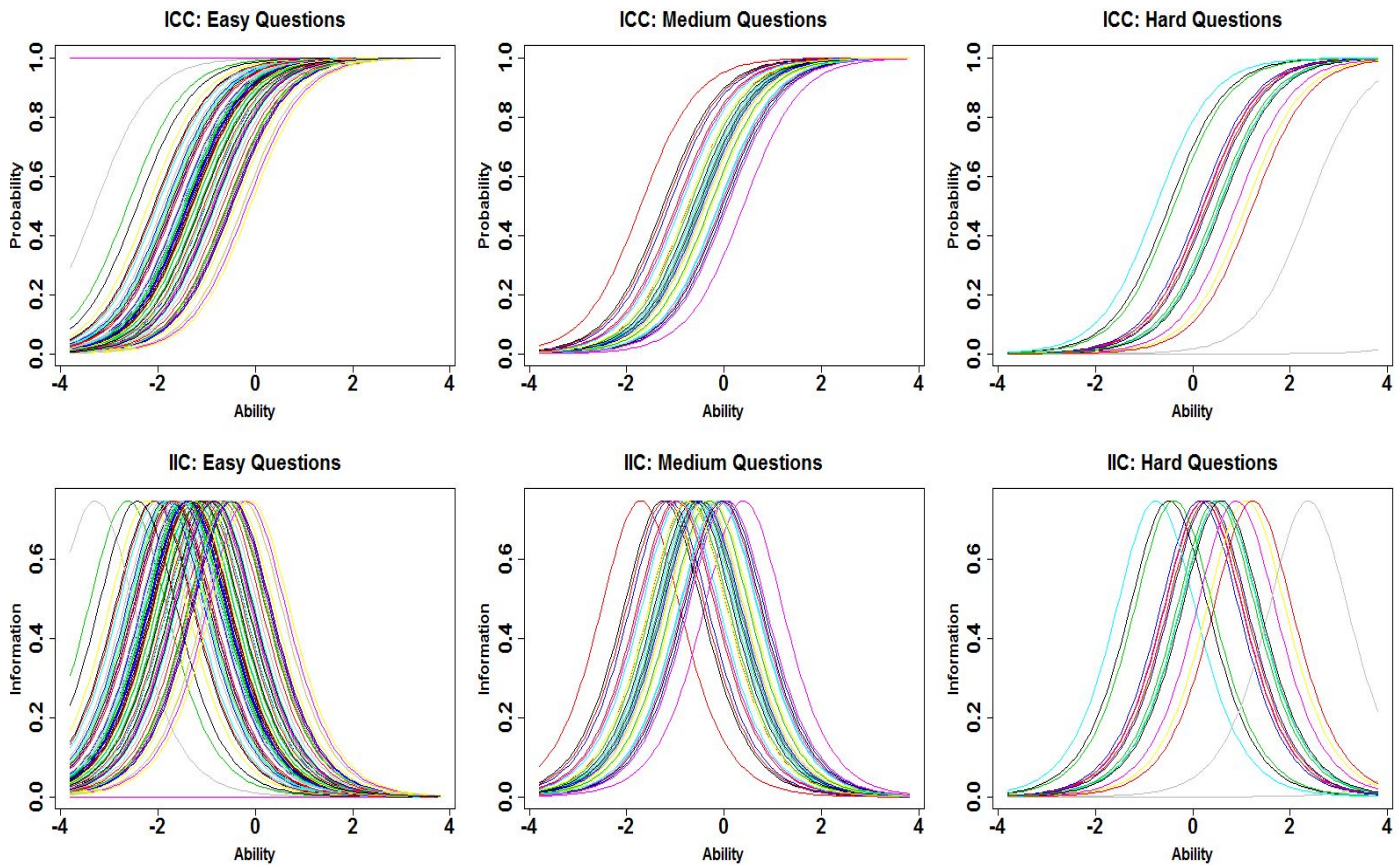

Figure 3. ICC and IIC plots from 1PL model

After conducting this analysis, we selected 30 minutes as a session. Any time interval greater than 30 minutes was marked as the beginning of a new session.

We then split students' actions into sessions. Next, we counted reading and SRL activities prior and after each question submission. We calculated the mean and standard deviation for the four reading and SRL features. To test if there were statistically significant differences in means, we applied the nonparametric Kruskal-Wallis test. In cases with statistically significant differences in mean, we performed a post-hoc Dunn test with Benjamini-Hochberg correction to identify pairwise statistically significant groups, using the R package "dunn.test" [15]. Table 2 presents the mean, standard deviation, and p value from Kruskal-Wallis test.

4.2.2 Results for RQ2

In this section we present our results to answer RQ2 and the sub-questions:

2a. How did SRL strategies vary with question difficulty?

2b. How did reading vary with question difficulty?

As Table 2 shows, the mean of all features vary at statistically significant levels across the three categories of questions. Number of reading activities is the highest for the *Hard* questions, followed by *Medium*, and *Easy*. This indicates students had to read more prior to attempting a *Hard* question.

Table 2: Mean with (Standard Deviation), and p value from KW = Kruskal-Wallis test for student behavior features on *Easy*, *Medium*, and *Hard* questions. R = Reading, A = Annotating, H = Highlighting, V = Vocabulary lookups

Feature	<i>Easy</i>	<i>Medium</i>	<i>Hard</i>	KW p
R	0.684 (0.71)	0.814 (0.74)	1.27 (0.70)	< 0.001
A	0.335 (0.20)	0.021 (0.17)	0.012 (0.12)	< 0.001
H	0.007 (0.10)	0.004 (0.06)	0.002 (0.05)	< 0.001
V	0.015 (0.13)	0.014 (0.12)	0.009 (0.1)	0.01

It also indicates that they revisited the reading material after attempting a *Hard* question more frequently than they did for *Easy* and *Medium* questions. Annotating, highlighting, and vocabulary lookup counts were higher in *Easy* and *Medium* questions as compared to *Hard* ones. We report the Dunn test and statistically significant pairs for each feature below. We report effect-size (r) using a nonparametric test, Cliff's-Delta [12].

For the reading feature (R), we found statistically significant differences among all three pairs *Easy-Hard*, *Easy-Medium*, and *Medium-Hard*. The p values of these pairs were *Easy-Hard* ($p < 0.001$, $r = 0.43$), *Easy-Medium* ($p < 0.001$, $r = 0.10$), *Medium-Hard* ($p < 0.001$, $r = 0.34$)

When we consider the annotating feature (A), we also found statistically significant differences in means among all three pairs. *Easy-Hard*, *Easy-Medium* and *Hard-Medium* pairs had ($p < 0.001$, $r = 0.02$), ($p < 0.001$, $r = 0.012$), and ($p = 0.018$, $r = 0.01$), respectively.

And, when considering the highlighting feature (H), we found two pairs differed at statistically significant levels: *Easy -Hard* ($p = 0.004$, $r = 0.004$) and *Easy-Medium* ($p = 0.0209$, $r = 0.003$).

Finally, for the vocabulary lookup (V) feature, we found one pair with a statistically significant difference: *Easy-Hard* ($p = 0.005$, $r = 0.01$).

5. DISCUSSION

We summarize our findings and implications of results below.

In this study we used a data-driven approach on class-level student response data to group questions by difficulty levels. Our difficulty levels are consistent with findings from IRT analysis. ICC curves for *Easy* questions require lower student ability (Figure 3) and vice versa for *Hard* questions.

Table 1 shows 11 MCQ questions belonging to the *Hard* category. We looked into the question texts and observed 10 out of 11 questions required students selecting multiple options, e.g., "Select all that apply." Our analysis from RQ2 indicates students exhibited more reading (R) behavior prior and after answering *Hard* questions compared to *Easy* and *Medium* ones. Thus, our findings indicate that although students can often rule out distractors in MCQs [6], answering such questions is *Hard* when options involve selecting multiple correct answers. Our findings may be helpful for ITS designers. Developers of ITS can facilitate more hints on MCQ questions having multiple correct answers, so that students do not find those *Hard*.

From Table 1, we observed 75 out of 81 *Easy* questions were SAs. Our results for RQ2 indicated that students annotated (A), highlighted (H), and looked up vocabulary (V) more in answering *Easy* questions. We conclude that the format of questions may have contributed to students' SRL usage, even if the difficulty level was classified as *Easy*. Ideally, we would have been able to control question format and student characteristics; secondary data mining allows for large-scale data, but precision of results can be compromised by lack of these details. Nevertheless, we were able to demonstrate that SRL behaviors covary with question difficulty and/or format. It seems likely that as students encountered SA questions, they received metacognitive signals that encouraged their use of SRL behaviors [27] and this resulted in the relatively greater success of these questions. However, we cannot disentangle this from difficulty in our data. Although multiple option MCQs were difficult for students, they may not have triggered metacognitive awareness of the need for SRL behaviors. This is in line with some prior research suggesting less confidence bias in SA questions than in MCQs [29].

6. LIMITATIONS

Our study has two limitations. First, student responses to assignment questions are dependent on the teacher's selection of questions. We do not have responses to all questions for every student. Thus, the latent ability analysis of IRT is limited to student response data. Second, we did not consider the text complexity of the reading article in analyzing question difficulty. Science reading requires analyzing information from texts, diagrams, mathematical equations, and videos [22, 49]. Future research direction can investigate the association of question texts and the reading texts to understand text complexity.

7. CONCLUSION

In this study we investigated associations of students' reading and SRL behavior with question difficulty in middle school science reading. We analyzed question difficulty at the class level and compared our analysis method with IRT. Our results show that MCQ with multiple correct options are generally harder for students in our middle-school set. And we show that when faced with such hard questions, irrespective of their type, students engage in more reading activities but not the other SRL actions we measured. *Easy questions, by contrast, were more commonly* SAs than MCQs. Students spent more time annotating, highlighting, and looking up vocabulary terms in *Easy* questions. This may reflect that the easy questions in our dataset are more focused on rote memorization or on localizing responsive passages in the larger text than on concept synthesis or summarization, or, alternately, SA questions may prompt students to engage in SRL behaviors that MCQs do not. Due to the confounding of difficulty and format type, we were unable to disentangle these reasons. We hope our work opens up further opportunities for researchers and ITS developers to explore student interaction with question difficulty.

ABSTRACT

Collaborative problem solving (CPS) is considered a necessary skill for students and workers in the 21st century as the advent of technology requires more and more people to frequently work in teams. In the current study, we employed theoretically-grounded data mining techniques to identify four profiles of collaborative problem solvers interacting with an online electronics task. The profiles were created based on 11 theoretically-grounded CPS skills defined a priori. The resulting four profiles correlated in expected directions with in-task performance and had interesting relationships with external measures associated with prior knowledge and CPS skills. These results inform and partially replicate findings from our previous research using a similar approach on a smaller dataset. Implications and comparisons between the two studies will be discussed.

Keywords

Collaborative Problem Solving, Ontology, Assessment, Simulation-based Assessment, Discourse

1. INTRODUCTION

With the increasing need for technology in workplace contexts, collaborative problem solving (CPS) is considered an important 21st century skill as workers are often required to complete complex tasks in teams to solve complicated, often technical problems. Accordingly, the need to teach and assess CPS has gained increased attention by researchers [4,5]. In research seeking to assess or teach CPS skills, researchers often employ digital technologies to capture evidence and improve assessment of CPS, as this skill is complex and includes many facets.

In defining the facets of CPS there is little dispute that the construct includes social and cognitive dimensions [1,22]. The social dimension is meant to be interpersonal, including features such as sharing information and perspective taking. These types of features are associated with building a shared understanding among team

members which is essential for building common ground, an important component of completing a task [6]. The cognitive dimension includes components such as planning, representing the problem, and formulating hypotheses. These components are complex in nature and therefore difficult to assess with traditional assessments such as multiple-choice questions without compromising fidelity and generalizability [7]. Therefore, assessment researchers have turned to online environments, including games and simulations, which allow for collaboration among team members to capture the discourse and complex actions necessary to evaluate CPS competency.

To evaluate CPS competency in online environments, both a competency model and advanced analytic techniques are often needed. Specifically, a competency model is necessary to identify skills and features aligning to specific constructs. Analytic approaches are needed to deal with the large streams of data stored in log files while also accounting for the underlying competency model and theoretical explanations [12].

Accordingly, in an effort to assess students' CPS skills in an online environment, we employ a theoretically-grounded data mining approach [9] incorporating a conceptual model and machine learning approaches in an iterative process. Specifically, we define a competency model based on existing literature that identifies features a priori. Our competency model is based on our prior work [1,2,3] and used to extract features in a meaningful way, and machine learning algorithms are used to profile students. We then interpret and refine algorithms based on theoretical interpretations. Thus, the process is a collaborative effort between computer scientists, learning scientists, psychometricians, and cognitive psychologists. In the current study, this principled process is used to replicate findings from a previous study [2] by discovering profiles of collaborative problem solvers that are strongly grounded in theory associated with cognitive and social psychological research. We then validate these profiles with external measures and compare these profiles with our previous findings from students interacting with the same online collaborative electronics task.

2. METHODS

2.1 Participants

Students in electronics, engineering, and physics programs were recruited from universities and community colleges across the United States to complete the study. In total, there were 378 students who participated. Of those students who reported their

Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 403 - 408

gender, 76% were males and 21% were females with 3% other, preferring not to respond, or unreported. Of those who reported their race, 62% were White, 7% were Black or African American, 8% were Asian, 10% reported being more than one race, 1% reported Other, with 4% preferring not to answer or unreported. For ethnicity, 7% reported being Hispanic. The modal age range among students was 18 to 20 years old.

2.2 Tasks and Measures

To complete the study students first completed a pretest about electronics concepts to gather information about their content knowledge, next progressed to the online electronics task, and then completed self-report measures where they rated themselves and their teammates on CPS capabilities along social and cognitive dimensions. We will first discuss the external measures and then the online electronics task.

2.2.1 External Prior Knowledge Test

The external prior knowledge test was created by a group of experts concerning the series circuit problem. First a conceptual map of the problem was created. Then, a q matrix defining skills and complexity was devised to create an equal number of questions for each electronics skill necessary to solve the series circuit problem. Next, the final items were validated by experts as well as through psychometric analysis. As a result, the original test included 28 items but only 23 saliently reflected the original intent of the test developers based on a CFA [24]. Thus, the total score per student for the 23 items is the measure of prior knowledge.

2.2.2 CPS Inventory

The CPS Inventory serves as a self-report measure of CPS skills that aligns to a competency model of CPS (which will be discussed in more detail in the next section). The Inventory consists of 14 items, seven of which correspond to social CPS behaviors (e.g., I tried to establish a good relationship with my teammates) and seven of which correspond to cognitive CPS behaviors (e.g., I helped develop a plan to solve the problem). There is a “self” version of the Inventory where participants rate their own CPS behaviors on a 4-point Likert scale (1=strongly disagree, 4=strongly agree) and a “team” version where participants rate their team’s CPS behaviors as a whole on a 4-point Likert scale (1=strongly disagree, 4=strongly agree). The CPS Inventory was administered after students completed the electronics task described next.

2.2.3 Three-Resistor Activity

Students solved a collaborative problem on electronics concepts associated with Ohm’s Law and Kirchhoff’s Voltage Law. Each student in a team of three worked on a separate computer, each running a simulation of an electronics circuit. Each student’s circuit was connected to form a series circuit.

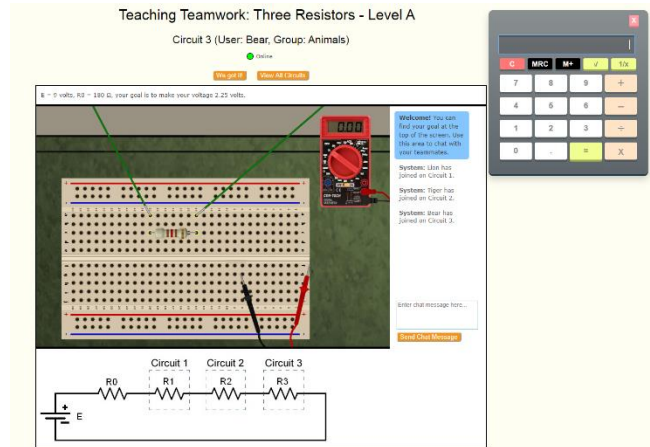

Figure 1. Screenshot of Three-Resistor Activity

Students were randomly assigned into teams by their instructors and team members were anonymized with provided usernames (e.g., Lion, Tiger, Bear). Within the interface, each student had a chat window, a digital multi-meter (DMM), probes extending from the DMM (red and black), a resistor, a zoom button, a calculator, and a submit button (See Figure 1 for a screenshot of the task interface). These features of the interface made it possible for students to communicate with teammates, take measurements, view and change the resistance on their boards, zoom out to view other teammates’ boards, perform calculations, and submit answer choices.

In the task, students had the goal of reaching a specified goal voltage value on each of their circuit boards. Because each of the circuits were connected in series, any changes made on one circuit board would affect readings on all teammates’ circuits which required the need for collaboration around coordinating actions so that everyone could reach their goal voltage values. The task has four levels which increase in difficulty as one variable changes in the task interface. In Level 1 each student had the same goal voltage value to achieve and the values of the resistance (R_0) and supply voltage (E) of an external, fourth circuit in the series that students could not control were provided. In Level 2 the resistance and supply voltage of the external, fourth circuit were still provided, but each teammate now had a different goal voltage to reach. In Level 3, teammates had different goal voltages, the external resistance was provided, but the external supply voltage was unknown and needed to be found to solve the problem. In Level 4, teammates again had different goal voltages, but now both the external resistance and supply voltage were unknown and needed to be found. The task was designed so that students may only proceed to attempt the next level after completing the previous level. Therefore, levels attempted can be used as a proxy measure for performance on the electronics task. To identify the CPS skills exhibited while solving the Three-Resistor Activity, a CPS conceptual framework outlined in the form of an ontology was created, as described next.

2.2. CPS Conceptual Framework

A CPS ontology (similar to a concept map) was created using the In-Task Assessment Framework (I-TAF) approach [3,12]. This approach is an augmented version of evidence-centered design (ECD) that supports identification of features of complex constructs in online environments.

Creating the ontology required iterative refinement with the support of subject matter experts and data. The ontology was created based on literature from areas such as computer-supported collaborative learning, organizational psychology, individual problem solving, and linguistics [11,14,15, 18,19,20,21,22,23]. Data collected from the Three-Resistor Activity then informed changes to the ontology so that it most accurately reflects the construct as well as associated skills, strategies, tactics, and features based on real data collected from students interacting with the task.

To visually display the various components of CPS, the ontology is designed hierarchically. The construct (i.e., CPS) sits at the top with the two dimensions of CPS (social and cognitive) as second layer nodes. The social and cognitive nodes are linked to CPS skills associated with each dimension. Specifically, there are four skills in the social dimension and five skills in the cognitive dimension. The social dimension includes maintaining communication, sharing information, establishing shared understanding, and negotiating. The cognitive dimension includes exploring and understanding, representing and formulating, planning, executing, and monitoring. For a more in-depth discussion of this work, please refer to [1,2,3].

The nine high-level CPS skills are linked to 23 sub-skills on the fourth and fifth layers of the ontology. These sub-skills more explicitly define each of the nine CPS skills. For example, the sharing information CPS skill includes three sub-skills, sharing one's own information, sharing task or resource information, and sharing understanding. The sub-skills are connected to an evidence model which provides nodes corresponding to strategies or behaviors needed to indicate evidence of each sub-skill. The strategy nodes are then linked to tactic nodes which correspond to in-task affordances available to carry out a given strategy and subsequently feature nodes that can be inferred from individuals' behaviors. These features are identified in the log files for extraction and additional analysis. See Figure 2 for an example of the structure of a portion of the CPS ontology.

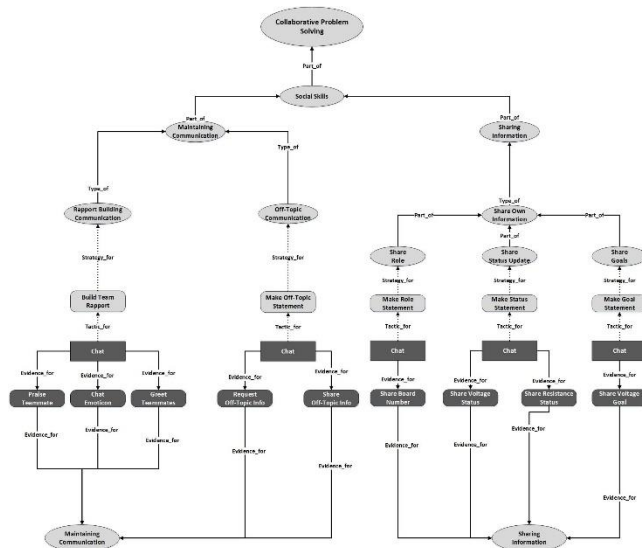

Figure 2. CPS Ontology Fragment

For this particular ontology, the majority of the skills are represented by discourse features associated with team members chatting amongst each other. As there are limited natural language processing tools to identify such low level and abstract features of CPS, qualitative coding was conducted.

2.3 Qualitative Coding

The qualitative coding was conducted on 51,805 rows of log data corresponding to student-generated chats and actions (e.g., resistor changes, calculations) to identify the 23 CPS sub-skills. Specifically, three raters coded each log file event, with each event only receiving one code. To examine inter-rater reliability, a random sample of 20% of the data were triple coded. The inter-rater reliability among the raters was found to be Kappa = .93, indicating substantial agreement [13]. All discrepancies among the coders were discussed to reach consensus for a final code. The remaining data were coded individually by the raters.

During qualitative coding, raters were looking for evidence of one of 23 sub-skills within nine high-level CPS skills under the social and cognitive dimensions of CPS. We next describe each of the sub-skills in turn. In the social dimension, maintaining communication corresponds to content-irrelevant social communication [15,16] and includes three sub-skills, rapport building communication (e.g., greeting teammates), off-topic communication (e.g., talking about homework from another class), and inappropriate communication (e.g., denigrating teammates). Sharing information corresponds to content-relevant information used in the service of solving the problem [22,25] and includes three sub-skills, sharing one's own information (e.g., sharing one's goal voltage), sharing task or resource information (e.g., sharing where the calculator is located in the task interface), and sharing the state of one's understanding (e.g., metacognitive statements such as, "I don't know"). Establishing shared understanding corresponds to communication used to learn the perspective of others and ensure that communication is understood by others [6]. This CPS skill includes two sub-skills, the presentation phase (e.g., requests for information) and the acceptance phase which includes responses indicating comprehension or lack of comprehension of a statement. Negotiating corresponds to communication used to identify conflicts and resolve those that arise [11], and includes three sub-skills, expressing agreement (e.g., "you are right"), expressing disagreement (e.g., "that's not right"), and resolving conflicts.

In the cognitive dimension, exploring and understanding corresponds to actions used to explore the task interface and understand the problem [21] and includes two sub-skills, exploring the environment (e.g., spinning the dial on the DMM) and understanding the problem. Representing and formulating corresponds to communication used to build a mental representation of the problem and formulate hypotheses for how to solve the problem [19,21]. There are two sub-skills for this CPS skill, representing the problem (e.g., "this is a series circuit") and formulating hypotheses (e.g., "I think if everyone has 470 ohms it will be 3.25"). Planning corresponds to communication used to develop a strategy for solving the problem [11, 21], and includes three sub-skills, setting goals (e.g., "We need 6.69 V across our resistors"), managing resources (e.g., "We need to find numbers and decide who does what"), and developing strategies (e.g., "Let's find E first using Kirchhoffs voltage law"). Executing corresponds to communication and actions used in the service of carrying out a plan [21]. This CPS skill includes three sub-skills, enacting strategies (e.g., performing calculations), directing actions (e.g., "Adjust yours to 300 ohms"), and reporting actions (e.g., "I set mine to 120"). Monitoring corresponds to communication and actions in the service of monitoring teammates or progress toward the goal [21,22], and includes two sub-skills, monitoring team organization (e.g., checking on the status of teammates or clicking the Zoom button) and monitoring success (e.g., "We got it" or clicking submit).

3. ANALYSES AND RESULTS

After completing the qualitative coding, the quantitative analyses were conducted in two stages: profile discovery and then validation. For the profile discovery, we performed a hierarchical cluster analysis on the frequencies of each individual's display of the high-level CPS skills using the Ward method [26] as this was an appropriate clustering method given the sample size [17]. We collapsed the 23 sub-skills into the high-level CPS skills for the cluster analysis in order to replicate the process used in previous research [2]. Next, the revealed profiles were compared according to their task performance as identified by number of task levels attempted, performance on the electronics pre-test, and ratings on the self and team CPS Inventory with Kruskal-Wallis tests and Mont Carlo simulations to ensure accurate statistical significance.

3.1 Profile Discovery

We discovered profiles of various types of collaborative problem solvers based on the CPS skills as determined by the competency model (i.e., CPS ontology). Since two of the CPS skills (monitoring and executing) each had both chat and actions as features to determine these skills, we separated them into separate chat and action skills (i.e., monitoring chats, monitoring actions, executing chats, executing actions). Thus, the total number of CPS skills clustered were 11. A hierarchical cluster analysis using the Ward method [26] was conducted on the standardized frequencies of CPS skills displayed for each student. The final number of resulting profiles was determined based on a theoretical interpretation of each of the profiles. Therefore, the profiles were not chosen by fit metrics alone but rather how meaningful these profiles were with respect to social and cognitive psychological research. This was a similar approach to that which was used in our prior work [2]. Although the method was similar, the resulting profiles had some differences. Four profiles emerged with varying sample sizes, which were named Social Loafers, Active Collaborators, Super Socials, and Low Collaborators. In our interpretation of the profiles, we used standardized average frequencies of the CPS skills to discuss patterns across the four profiles.

3.1.1 Social Loafers

The Social Loafers ($n = 190$) were a group of individuals that displayed below average frequencies of every CPS skill. These individuals did not contribute much to the team's problem solving. Social loafing has a long history in social psychology as a phenomenon where individuals assume that other team members will complete the task and therefore reduce their own effort [14].

3.1.2 Active Collaborators

The Active Collaborators ($n = 24$) displayed high frequencies on all of the identified CPS skills in the competency model [3] except for monitoring actions ($z = -.28$). Indeed, these individuals had z values greater than 1 on two of the CPS skills, and greater than 2 on another two CPS skills consistently indicating students being on average, at least an entire standard deviation above the overall mean. Specifically, sharing information ($z = 1.44$) and establishing shared understanding ($z = 1.08$), were above the mean. Furthermore, executing chats ($z = 2.23$) and monitoring chats ($z = 2.83$) were over a standard deviation above the mean. All other CPS skills had positive standardized values, indicating that these students were generally active in communicating with teammates and helping solve the problem.

3.1.3 Super Socials

The Super Socials ($n = 91$) showed high frequencies on the social dimension of CPS skills [1], but lower frequencies for the

cognitive CPS skills in comparison (except for representing and formulating). Specifically, these individuals showed the highest demonstration of negotiating behaviors in comparison to the other profiles ($z = 1.02$) and had positive standardized values on all other social skills, though not quite at the level of the Active Collaborators. The only cognitive CPS skills with positive standardized values were communication-based behaviors representing and formulating ($z = 1.08$), planning ($z = .51$), executing chats ($z = .21$), and monitoring chats ($z = .09$).

3.1.4 Low Collaborators

The Low Collaborators profile ($n = 73$) consisted of individuals that did not appear to collaborate with their teammates based on the features in the competency model [3]. However, they did show high levels of action-based cognitive behaviors including exploring and understanding ($z = .77$), monitoring actions ($z = 1.21$) and executing actions ($z = .76$). The Low Collaborators had negative standardized values for all other CPS skills. These individuals appeared to work alone without communicating with their teammates which is different from the Social Loafers who simply did not do much work at all.

3.2 Profile Validation

The profiles were validated with both log data performance metrics as well as external measures.

3.2.1 In-Task Performance and Profile Membership

There was a significant relationship between profile membership and the number of task levels attempted, a proxy for performance in the task, ($X^2(3,370) = 7.66, p = .05, \text{partial } \eta^2 = .02$). The Monte Carlo simulation for significance with 10,000 samples revealed a significance level of $p = .05$ (lower bound $p = .047$, upper bound $p = .059$). Specifically, the mean ranks, where higher values corresponded to more levels attempted, were the lowest for the Social Loafers (175.00) and highest for the Active Collaborators (219.88) which is similar to our previous findings [2]. The mean ranks for the Super Socials and Low Collaborators fell in between the aforementioned profiles (194.87 and 189.57, respectively). These patterns indicate that the Active Collaborators and Super Socials had higher mean ranks on performance than Social Loafers and Low Collaborators.

3.2.2 Pre-Test Performance and Profile Membership

The profiles were compared to the external electronics pre-test, a measure of prior knowledge. The test included 23 items that were summed to create a score for each student participant. Results revealed that there was a significant relationship between profile membership and performance on the electronics test ($X^2(3, 370) = 8.83, p < .05, \text{partial } \eta^2 = .02$). The Monte Carlo simulation for significance with 10,000 samples revealed a significance level of .027 (lower bound $p = .021$, upper bound $p = .031$). The highest mean rank for prior knowledge was for the Active Collaborators (212.73) and the lowest was for the Low Collaborators (172.10). Ranging in the middle, the Super Socials had higher mean ranks than the Social Loafers (209.42 and 175.45, respectively). Post hoc comparisons with a Bonferroni correction revealed a marginally significant difference between Social Loafers and Super Socials ($p = .08$). No other pairwise comparisons approached statistical significance (all p 's $> .10$).

3.2.3 Post-Task Self-Report and Profile Membership

The profiles were compared to student's ratings of their own CPS behaviors (Self CPS Inventory) and their team's CPS behaviors (Team CPS Inventory).

There was a significant relationship between self-ratings of CPS skills (sum of ratings for Self CPS Inventory) and cluster membership ($X^2(3,349) = 15.57, p < .05, \text{partial } \eta^2 = .05$). The Monte Carlo simulation with 10,000 samples revealed a significance level of $p = .001$ (lower bound $p = .001$, upper bound $p = .002$). Mean ranks were highest for the Super Socials (210.18) and lowest for the Social Loafers (160.58), with the Active Collaborators having higher mean ranks than the Low Collaborators as expected (184.96 and 162.22, respectively). Post hoc comparisons with a Bonferroni correction revealed a significant difference between Low Collaborators and Super Socials ($p < .02$) and Social Loafers and Super Socials ($p = .001$).

There was a significant relationship between ratings on the Team CPS Inventory and profile membership as well ($X^2(3,349) = 9.04, p < .05, \text{partial } \eta^2 = .03$). Monte Carlo simulation with 10,000 samples revealed a significance of $p = .028$ (lower bound $p = .024$, upper bound $p = .032$). The highest mean rank was for the Super Socials (199.47) and the lowest was for the Social Loafers (161.53), with Active Collaborators having higher mean ranks than Low Collaborators as expected (191.74 and 171.78, respectively). Post hoc comparisons with a Bonferroni correction revealed a significant difference between the Super Socials and Low Collaborators ($p = .02$).

4. CONCLUSIONS

Overall, we discovered four meaningful profiles of types of collaborative problem solvers: Social Loafers, Active Collaborators, Super Socials, and Low Collaborators. These profiles had significant relationships with in-task performance, electronics prior knowledge, and self-reported CPS capabilities.

The four profiles discovered partially replicate previous findings [2]. Specifically, in our previous study, Social Loafers and Active Collaborators also emerged as profile groups. The Social Loafers could also be called “Free Riders” as these individuals do not contribute much to solving the problem with their teammates. Conversely, the Active Collaborators, which were a small subset of the sample, performed well on all measured aspects of CPS. As expected, Active Collaborators showed better in-task performance than Social Loafers which replicates findings from our prior work [2]. This makes sense as the Active Collaborators displayed high frequencies of CPS behaviors and should therefore have performed well on the task. Social Loafers may have been expecting others to do the work and therefore should not have performed as well on the task.

There were two new profiles that differed but still augmented our previous findings. We attribute these differences to a change in sample size and its diversity. The sample size was nearly three times the size of the previous sample and included students in a wider variety of domains, including electronics, engineering, and physics. The new profiles that emerged in this experiment included the third profile called the Super Socials which does align with other profiles that have been examined. Specifically, in prior work we have found what we termed a high social/low cognitive profile that behaved similarly in displaying high levels of social CPS behaviors and comparatively lower levels of cognitive CPS behaviors. This profile was discovered by an examination of the two dimensions based on means of the CPS features rather than cluster analysis [1]. Beyond this, other work has found a profile designated as “Compensating Collaborators” who had high collaboration actions but performed poorly on problem solving variables [10]. The last profile, the Low Collaborators, also did not emerge in our prior cluster analysis work [2] but could be usefully compared to the Chatty Doers from that work. Similar to the Low

Collaborators, the Chatty Doers demonstrated a high level of executing actions, but in contrast, the Chatty Doers did engage in communication with their teammates, though most of the communication was in the maintaining communication category. Interestingly, the Low Collaborators did not seek to engage with their teammates and instead appeared to work alone by engaging in executing and exploratory actions.

In regards to prior knowledge, Active Collaborators and Super Socials demonstrated the first and second highest average scores on the electronics pre-test. It is possible that their higher prior knowledge enabled them to engage in more communication behaviors and problem-solving behaviors (in the case of the Active Collaborators) to contribute to solving the problem. The opposite could be said for the Social Loafers and Low Collaborators, the latter of which had the lowest average pre-test performance. For example, perhaps the Low Collaborators did not want to collaborate with others and preferred to work alone because they were embarrassed of their low levels of content knowledge. On the other hand, perhaps the Low Collaborators already had low content knowledge because of their refusal to work with, and therefore learn from, others on previous tasks. Causality and directionality certainly cannot be determined by these analyses. However, these findings do suggest that testing these hypotheses may provide important insights for CPS researchers.

The Self and Team CPS Inventories required students to rate themselves based on their own metacognitive judgments of their own CPS behaviors as well as their team’s CPS behaviors. The Super Socials had the highest ratings for CPS behaviors both for themselves and for their team while the Social Loafers had the lowest ratings on each inventory. These results were expected, though we would also expect high ratings for the Active Collaborators and lower ratings for the Low Collaborators (mean ranks showed such patterns).

All of these findings together suggest that further research should be conducted to explore whether the same kinds of patterns of results emerge with relationships among profiles such as the ones observed in this study, in-task performance, and other ratings. One limitation of this study is that the in-task performance measure includes aspects of the contributions from others while the CPS profile is based on an individual’s contributions. Despite the interdependent nature of the electronics task, we are continuing work in developing an alternative in-task performance measure that potentially incorporates only individual contributions. Furthermore, the CPS Inventory relies on self-judgments which can sometimes have biases [8]; however, we did want to incorporate some external measure of CPS behaviors that could be compared to participants’ in-task CPS behaviors. Finally, the CPS skills used to develop the profiles included only the higher aggregate level CPS skills, as the sample size was not sufficient to include the lower level coded data.

Overall, we found that this study, which included a larger sample size and new external measures relative to our previous work, partially replicated and informed our previous findings. Our theoretically-grounded data mining approach appears to reveal meaningful profiles on two separate data sets with students completing the same electronics task. We hope that this work will inform future work on ways to incorporate theory and data-driven approaches to make inferences about individuals’ CPS capabilities, and contribute to a better understanding of types of collaborative problem solvers, including how certain CPS behaviors relate to various relevant measures.

Student Teamwork on Programming Projects

What can GitHub logs show us?

ABSTRACT

Teamwork, often mediated by version control systems such as Git and Apache Subversion (SVN), is central to professional programming. As a consequence, many colleges are incorporating both collaboration and online development environments into their curricula even in introductory courses. In this research, we collected GitHub logs from two programming projects in two offerings of a CS2 Java programming course for computer science majors. Students worked in pairs for both projects (one optional, the other mandatory) in each year. We used the students' GitHub history to classify the student teams into three groups, *collaborative*, *cooperative*, or *solo-submit*, based on the division of labor. We then calculated different metrics for students' teamwork including the total number and the average number of commits in different parts of the projects and used these metrics to predict the students' teamwork style. Our findings show that we can identify the students' teamwork style automatically from their submission logs. This work helps us to better understand novices' habits while using version control systems. These habits can identify the harmful working styles among them and might lead to the development of automatic scaffolds for teamwork and peer support in the future.

collaborative learning, version control, study habits, secondary education, GitHub, team projects

1. INTRODUCTION

Teamwork is an essential component of professional software development and CS educators incorporate it into their curricula to better prepare students for future careers [12, 34]. Working in teams provides students the opportunity to work on larger-scale projects than they otherwise would, and is more consistent with industry practice. Team projects also allow students to learn from their peers as described by *Social Learning Theory* (SLT) [3]. *Social Learning Theory* highlights four principal requirements for learning in social environments - **attention** or the opportunity to observe each other's work, **reproduction** or the chance to implement what they learned from observations, **retention** or being continuously engaged in the team, and **motivation** for learning [3].

Niki Gitinabard, Ruth Okoilu, Yiqiao Xu, Sarah Heckman, Tiffany Barnes and Collin Lynch "Student Teamwork on Programming Projects. What can GitHub logs show us?" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 409 - 416

Prior research suggests that having all the team members engaged in the project is essential for success and for student learning. Seers et al. showed that the balance of contributions in a team is correlated with team performance and member satisfaction [36]. Chen et al. argued that uneven teamwork, where one member does the majority of the work, may limit the learning opportunities for their peers as well as themselves [9]. Further, students that do not contribute may become less motivated to make genuine efforts since they can rely on their teammates to pick up the extra work [40].

Many researchers have measured and studied effective coding and study habits for individuals [2, 38, 37, 22, 41, 6, 5, 42, 16, 8]. However, evaluating the quality of students' teamwork is more complicated. Hoegl et al. defined teamwork quality metrics as communication, coordination, balance of member contribution, mutual support, effort, and cohesion [15]. Most of these metrics are not easy to quantify. Some have relied on surveys [10] or supervisor assessments [28] for the evaluation of students' teamwork process, but little work has been done evaluating student teamwork quality and contribution in CS secondary education programming projects based on online activities [31]. As a result, in this work we aim to automatically identify the teams with weaker teamwork styles.

Teamwork in software development projects can be described in three ways. Coman et al. address two forms of teamwork: "Collaborative", where the teammates share the same goal toward solving an issue (in their case sharing a programming task), and "Cooperative", where they support each other while working on different goals [11]. We observed that students took similar approaches in our group coding assignments. Some worked on similar parts of the project (e.g. both working on implementation or both testing, etc.) at the same time. Since each of these parts were focused on a specific goal (e.g. implementation adds program features and writing test cases improves code coverage and finds issues), working on the same parts means having a similar goal and these teams are similar to Collaborating teams. In such teams all the members have significant contributions to the same parts and they might even do pair-programming at times. Other groups of students divided the work by the project part (e.g. one works mostly on implementation and the other works on testing) while all contributing significantly. They might assist each other when necessary, but most of the work in each part was done by one member, focusing on the specific goal of each part. This behavior is similar to Cooperative work as mentioned by Coman et al.. The third form of teamwork is having a *free-rider*, which as mentioned by van der Duim, is common in group projects [40]. We refer to this form of teamwork as "Solo-submitting" where one member did most of the work. The other members might have a few commits where they made a quick fix, but the majority of work was done by a single member.

In this work, we analyzed data collected from two offerings of a CS2 course on Java programming for CS majors. In this course, students must complete three programming projects, one independent assignment, one where pairing is optional, and one where it is mandatory. The students are required to use GitHub as a version control system and for assignment submissions. Also, their GitHub repositories are connected to a Jenkins [1] server, which provides them with responses from instructor-defined unit tests every time they submit their code. We analyzed student commit behaviors to define metrics for evaluating their contributions to the team and to classify their work style. We tagged 400 commit messages as referring to different parts of the student projects (i.e. Implementation, Testing, Bugfix, Merge, Documentation, Style, and Other) that were graded in this course. We then used natural language processing to learn from that sample and tag the remaining commit messages. We finally used the commits in different categories to define several metrics for students' contributions to the team such as the *Number of implementation commits* and the *Percentage of testing*. In order to obtain a ground truth metric for the teamwork style we engaged two subject matter experts to classify 100 of the 238 team repositories in these classes into one of the three categories: "Collaborative", "Cooperative", and "Solo-submit". Then, we used the metrics to train and test prediction models on the teamwork styles of these projects.

To be more specific, we test the following set of hypotheses:

- H1. We can automatically classify commit messages into different parts of the project.
- H2. We can automatically classify student teams into Collaborative, Cooperative, or Solo-submit.

The findings of this study will help us to develop metrics to evaluate the effectiveness of student project teams and eventually provide students adaptive guidance or flag teams for instructor intervention.

2. BACKGROUND

Prior researchers have analyzed students' work on programming projects with the goal of identifying good habits that are common to higher performers and bad habits that are not [2, 38, 37, 22, 41, 6, 7, 5, 42, 16, 8]. Some researchers have also used visualization tools to analyze students' activity patterns and to present guidance to the students themselves (e.g. Retina [26, 18]). One more recent approach to analyzing students' behavior is based upon studying logs from version control systems [14, 34, 26, 25]. However, prior studies in this area have primarily focused on the students' individual work habits and not on the role that they play in a team. While other researchers have studied teamwork in CS courses (e.g [27, 39, 4, 30, 43, 12, 19]), these studies have generally relied upon student surveys and evaluations to bound their performance and only a few have considered their online behavior [18, 23, 13]. Thus, there is little prior work on detailed analyses of how individual student features affect team performance.

While teamwork is the norm in industry, students may be unfamiliar with norms of collaborative work and many things can go wrong in team projects [12]. For example, some team members may decide to "gang up" and leave others out of the decisions or they might decide to be "free-riders" and do no work at all [35, 40]. A number of researchers have studied the impact of teamwork on student performance and ways to enhance the experience of collaborative class work. Higher performing students often believe that they worked with greater initiative than their teammates, mostly alone, and they tend to give up on collaborative work [20]. Additionally, there are users who prefer to work alone, mostly

called "lone wolves" and their inclusion in teams often has a negative impact on the team's overall performance on the project [4]. Instructors could use online contributions to easily identify some of these harmful patterns.

Another use for evaluating student contributions is to measure their teamwork quality. Most of the prior studies in classes evaluate the quality of the teamwork and their satisfaction with the teamwork experience based on the students' final peer evaluations [39, 43, 12, 19, 20]. While peer evaluation is a popular method among the instructors and is often used for grading group work [30, 19], it can be difficult to calculate student grades using their peers' estimations of their share of work [12]. There are also other methods such as video-taping students while collaborating [27]. As suggested by Hoegl, the balance of students' contributions (i.e. having almost equal shares in the project) to the team is also an effective measure for team quality [15]. Seers et al. also mentioned that the balance in the team members' contributions is related to team performance [36]. However, measuring member contributions to software projects is not easy.

Other approaches have also been proposed for measuring team member contributions. One method relies on instructor qualitative evaluations [24, 29, 17]. This opinion is often subjective and non-quantitative, but can provide good gestalt insights based on the students' online activities which makes the evaluation easier [18, 23, 13]. The same approach has also been used in software development projects in industry where the managers can view a summary of a team member's activities while evaluating their performance [31, 28, 21]. Kim et al. and Liu et al. suggested generating reports for the instructors based on version control system logs to track the students' activities and progress and intervene if needed [18, 23]. Such reports include information such as: who created the document, how many students edited the document, how many edits were made, how long the document was edited, how many words were included [18], total number of revisions, and the average number of work days [23]. Studies have shown that these types of reports can be used to track student team project progress and to intervene if necessary.

While having the instructor or team manager's opinion is a reliable method to evaluate the contributions of different team members, Lima et al. noted that managers often find this evaluation time-consuming and that is has no specific criteria for good teamwork [21]. As a result, more recent studies have focused on automatically extracting the students' share of work from a version control system [13]. For example, Ganapathy et al. evaluated group collaboration by the number of documents edited by several group members and found that better collaboration could predict a better outcome on the project [13]. El et al. similarly showed that the number of commits and the amount of lines of code added by a user are statistically significant characteristics for identifying contributions to the team.

3. DATASET

The dataset used in this study covers two consecutive fall semesters (2015 and 2016) of a CS2 Java programming course for majors. The course covers topics such as object-oriented design, testing, composition, inheritance, state machines, linear data structures, and recursion. Both course offerings were taught by the same instructors and were split into two on-campus sections. All sections included two midterm exams (referred to as Test 1 and Test 2), a final exam, lab sessions, and three projects. The first project was completed individually while the students had the option to work in pairs for the second project, and were required to do so for the third. Students were allowed to request specific teammates or

Table 1: Statistics of Each Class

Class	Java-2015	Java-2016
On-campus Students	181	206
Teaching Assistants	9	9
On-campus Instructors	2	1
Average Grade	79.7	79.9
Project 2 pairs	36	44
Project 2 selected peers	30	39
Project 2 assigned by instructor	6	5
Project 3 pairs	73	85
Project 3 selected peers	39	56
Project 3 assigned by instructor	34	29
Avg commits per repository	109	66
Max commits per repository	317	198

have them assigned by the instructor. When assigning students to teams, the instructor created balanced teams based upon similar prior performance on individual work (i.e. exam 1 and project 1). Both of the team projects included an individual component (a high-level system design and system test plan), and a team component (a system implementation). The system implementation part took about two weeks and the students were not permitted to work in a team if they failed to complete the individual task. Once students completed the individual parts and formed teams, an instructor-authored design was released and the students were required to implement it for the second stage of the project.

Students used the Eclipse IDE for the project implementation and were graded based on teaching staff and student-authored test cases, code coverage from student-authored test cases (EclEmma), coding style (SpotBugs, PMD, CheckStyle), and documentation (JavaDoc). They used Moodle as a learning management system (LMS) to access materials and Piazza as a shared discussion forum. They also used the GitHub version control system to support teamwork and track coding progress. Whenever a student made changes to their project, a difference (diff) between the currently saved version and the edited version was created showing which files had been added or removed, and which lines of code had been added or removed. Students could store these diff changes by creating a “commit”, which could serve as a checkpoint for progress. These commits were then uploaded, or “pushed”, to GitHub, along with a commit message added by the students explaining the changes that had been made.

Student projects were automatically evaluated using the Jenkins continuous integration system which monitored student GitHub repositories for changes [1]. When Jenkins detected a change, it would download the current iteration of the repository, evaluate the submissions via teaching staff test cases, and provide feedback to students via a web-based platform. Students’ grades relied both on their code passing the staff test cases as well as having enough code coverage by writing their own tests. Staff test code was hidden from students, but students could see the test numbers and topics, including hints, for any failing tests. Students were allowed to submit their code for evaluation as often as they chose. Each repository had at least one (1) commit, at most 317 commits, and on average 80 commits per repository over both semesters. We focus our analysis on students’ commit history as it reflects their coding behaviors.

As shown in Table 1, the 2015 class had 182 students and 9 teaching assistants (TAs) while the 2016 class had 206 students and 10 TAs. Both these offerings included on-campus and distant education sections but we focused on the on-campus sections for consistency.

Commit Type	Percentage	Example
Implementation	0.33	Added Constructors for inner classes
Test Cases	0.15	More test cases
Bug Fixes	0.29	Fixed logout
Documentation	0.03	Added Javadoc to the class
Style	0.04	Fixing PMD errors
Merge	0.03	Merge branch ‘master’ of ...
Other	0.11	asdf

Table 2: The distribution and an example of different commit types among manually tagged data

tency. In 2015, for the second part of projects, there were 39 pairs for Project 2 and 76 pairs for Project 3; the remaining students either failed to complete the design portion of the projects and worked alone or decided to work alone on project 2. In 2016, there were 46 pairs for Project 2, 88 pairs for Project 3, one group of three members for Project 2 and another group of three for Project 3, and the remaining students worked individually. Since the aim of our study is to understand the students’ teamwork, we focused our analysis on Projects 2 and 3 and only on teams of 2 for consistency.

4. METHODS

4.1 H1. We can automatically classify commit messages into different parts of the project.

Our dataset for 2015 contains a total of 4473 commits from Project 2 and 8224 from Project 3. For 2016 we have a total of 7432 and 10430 commits for Projects 2 and 3 respectively. Since our focus is on the students’ teamwork, we focused our analysis on commit messages of student pairs in Projects 2 and 3.

We first randomly selected and manually tagged 400 commit messages from our dataset classifying them into 7 different categories that described the commits. The tagging was done by a graduate student who had acted as a TA for this course several times before and was familiar with the structure of the projects. The categories were Implementation (I), Writing test cases (T), Bug fixing (B), Style fixing (S), Documentation (D), Merge (M), and Other (O). The distribution of these commit types among the 400 manually tagged commits and one example of each category are shown in Table 2.

In 2016, students were taught about pair-programming and were specifically asked to mention it in their commit messages. We used keyword matching of words (e.g. “pair” as well as the whole word “pp”) as some students abbreviated it to identify pair programming commits. We were able to find a total of 247 commits among all the student commits mentioning pair programming, 137 from Project 2 and 110 from Project 3, all in 2016 class.

For classifying the commit messages, we used a cascade model as shown in Figure 1. Some of these categories were easily identified by specific keywords. For example, merge commits are often auto-generated and always have the word “merge” in them, documentation commits often mention document or Javadoc keywords, style commits often mention the static analysis tools like PMD or CheckStyle, and commits that belong in none of our categories often do not have meaningful words and are easily detected using English corpus. We first removed English stop-words and lemmatized the text in the commit messages. We also added class-specific keywords to the acceptable English corpus, such as BBTP (black box test plan) or TS tests (teaching staff tests). To reduce the noise in our data and increase the accuracy of our models, we used static keyword matches to label *merge*, *documentation*, and *style* and

English corpus label *other*. For the remaining tags (i.e. Implementation, Test cases, Bugfix), we used a Binary Logistic Regression classifier for each label, using TF-IDF vector of features [33], with a maximum of 45 features and an n-gram range of 1 to 4. Each binary classifier categorized a commit message as belonging to a category or not. Similar to the previous stage, we identified commits belonging in each category and removed the already-labeled commits from the dataset for the next prediction task. Any commits remaining unlabeled in the end were labeled as the Other category. After training and testing our classifiers on our tagged sample using 5-fold cross-validation, we used the trained models to predict the commit types for the remaining unlabeled commit messages.

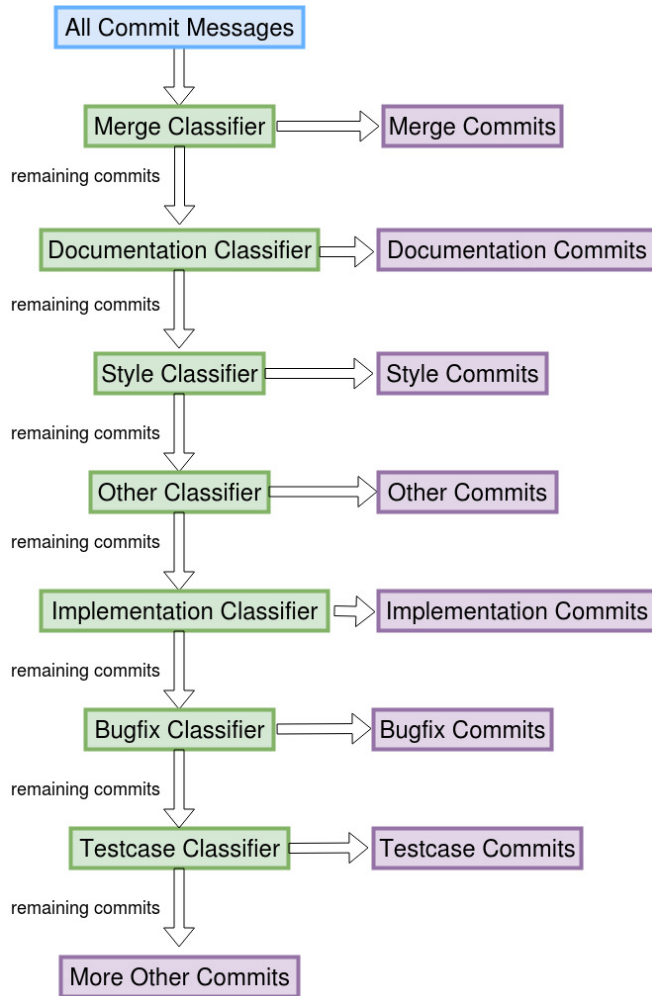

Figure 1: Cascade model for commit classification

4.2 H2. We can automatically classify student teams into Collaborative, Cooperative, or Solo-submit.

We labeled the teamwork style of the students who both worked on similar parts of the project as *collaborative* (e.g. both doing some implementation and some testing), while the teams where members both had significant contributions but mostly worked on separate parts of the project (e.g. one working on implementation and the other one on testing) were labeled *cooperative*. There were also teams where one student did the majority of work and the other student either did no work, or made small amount of changes. We labeled those teams *solo-submitting*.

To identify the teamwork styles, we randomly selected 50 repositories from each offering of the course and manually tagged them as collaborative, cooperative, and solo-submit. The tagging was done by two subject matter experts (SME), experienced TAs who are familiar with the course material and grading criteria, one of whom has acted as a TA for this course multiple times. First, a sample of 20 repositories were tagged by both SMEs with a kappa agreement of 0.88 and then the remaining repositories were tagged separately. As mentioned before, the students were able to get feedback on their code by pushing it to GitHub and checking it with the teaching staff test cases. As a result, there are many cases where the students wanted to try different fixes and submitted many commits with small changes continuously until they could pass the tests. Thus, the SMEs were asked to focus on the amount of work done by each student in each category, rather than the number of commits. To make the tagging process more consistent, we added more specific definitions for the different teamwork styles. A team where both members contributed between 30%-70% to at least two common parts of the project were considered collaborative. The teams where one member did the majority of work in some parts and the other member worked mostly on other parts were considered cooperative. If one member did not work as much, the team was labeled as solo-submit.

Identifying teamwork style by manual tagging requires a great deal of expert time and it can be difficult to come to agreement among different experts. As a consequence, for this part we focused on extracting the students' teamwork automatically by using features from their GitHub submissions, as well as their prior individual performance (exam 1 and project 1) and the way they chose their team (i.e. self-selected vs. assigned by the instructor). In discussions, one of the instructors suggested that students with prior individual grades below 60 should be considered *at-risk*. Consequently, we added new binary features reflecting the team members' risk as well. Overall, we calculated the following features for each team member, sorting the team members such that the student with fewer total added lines of code in the project would be user 0 and the student with more would be user 1 in each team.

Our final set of features included:

- The **total number of commits** for each user in the whole project as well as the number of commits in each part (Implementation, Testing, Debugging, Documentation, Merge, Style, and Other). These features can show the students' contribution as the number of commits to the whole project and to the different parts.
- The **percentage of commits** for each user in the whole project and in different parts. This feature can distinguish between 2 commits in a team with a total number of 20 commits vs. in another team with a total of 100 commits.
- The total number of **additions, deletions, files changed, and amount of change** (i.e. additions + deletions) for each user in the whole project as well as each part. Additions and deletions in GitHub are measured by the lines of code each user changes in a specific commit.
- The **average amount of additions, deletions, files changed, and amount of change** per commit for each user in the whole project as well as each part.
- The **percentage** of each students' additions, deletions, files changes, and amount of change in the whole project as well as each part. Similar to the percentage of commits, this can normalize the amount of change for each team based on their total amount of activities.
- The total and average **length of commit messages** for each

	Merge	Style	Documentation	Other
F1 score	0.98	0.99	0.99	0.95
Precision	1.00	1.00	1.00	1.00
Recall	0.96	0.98	0.99	0.90

Table 3: The performance of prediction models in finding Merge, Style, Documentation, and Other commits

user in the whole project and each part. This feature can distinguish between the members who write details about their changes and the ones who submit quick commits without much explanation.

- The total number of **pair programming commits** by each user as well as the total for the whole project. While using the total amount of pair programming is more intuitive, we believe that if all the pair programming is done on one person’s computer, it might provide some information about the dynamics of the teamwork.
- Prior individual performance for each user (i.e. exam 1 and project 1 grades). Exam 1 and project 1 take place at a similar time and before project 2 and project 3.
- Risk label ($grade < 60$). We added each student’s risk label for exam 1 and project 1 as separate features, as well as one overall risk label for the team which shows whether or not any member of the team could be considered at-risk based on exam 1 or project 1.
- The team’s selection method as a label “selected” which shows whether the students in this team requested working together or they were assigned by the instructor.

After defining and standardizing each feature, we ended up with 188 features. We used random forest feature selection as well as the recursive feature elimination (RFE) method with logistic regression to select the most important features for predicting students’ teamwork style (i.e. collaborative, cooperative, or solo-submit). Random forests in Scikit-learn library return feature importance for all the features and we can select a desired number of top features for our model [32]. The RFE method in Scikit-learn library uses the coefficients of a linear model (in our case logistic regression) to estimate feature importance and prune the least important features until reaching the desired number of features [32]. We tried different numbers of features to find the features that resulted in better F1-scores. We then used cascade binary random forest and logistic regression classifiers using the selected features to predict each project’s teamwork style. We chose these models because they are fast and they also provide us with information on what features they used and how those features contributed to the outcome, which can be useful when planning future interventions. Similar to commit classifications, these binary classifiers were trained based on belonging or not belonging to each category. We tested the accuracy of these models using 5-fold cross validation.

5. RESULTS AND DISCUSSION

5.1 H1. We can automatically classify commit messages into different parts of the project.

We first trained classifiers for the manually tagged commit messages in the categories of Style, Documentation, Merge, and Other using static matches. The F1-score, precision, and recall for these predictions are shown in Table 3.

After removing these categories, we classified the remaining tagged commits into Implementation, Tests, and Bug fixes. In the end, any commits left in no category were categorized as

	Implementation	Bug Fix	Tests	Other
F1 score	0.84	0.92	0.92	0.78
Precision	0.88	0.87	0.86	0.64
Recall	0.82	0.97	0.98	1.00

Table 4: The performance of prediction models in finding Implementation, Bug Fixes, Tests, and Other commits

	2015				2016			
	Project 2		Project 3		Project 2		Project 3	
	Count	Ratio	Count	Ratio	Count	Ratio	Count	Ratio
Implementation	848	0.25	2060	0.33	2666	0.44	4317	0.49
Test Cases	298	0.09	327	0.05	637	0.10	450	0.05
Bug Fixes	767	0.22	1433	0.23	1262	0.21	2076	0.24
Documentation	117	0.03	196	0.03	464	0.08	471	0.05
Style	141	0.04	268	0.04	457	0.08	624	0.07
Merge	367	0.11	520	0.08	173	0.03	533	0.06
Other	901	0.26	1399	0.23	433	0.07	340	0.04

Table 5: The distribution of different commit types in each year and project

Other. Since the list of Others commits changed after this stage, we calculated the accuracy of the models for this label twice, once based on the static analysis of the commit message as shown in Table 3, and another time after assigning all the commits left uncategorized to this group as shown in Table 4. The average F1-score, precision, and recall for the 5-fold cross validation for these predictive models are shown in Table 4. As shown in this table, the precision of the Other category reduced as we added the remaining uncategorized samples to this group, which means some of these samples belonged to other categories but were not found by them, but the high recall score shows that all the commits in the Other category were identified successfully.

These results support H1, showing that our prediction models are able to predict the categories of commit messages with an F1 score of 0.78 or higher. For most of the categories, the F1 score is higher than 0.9. After this step, we trained prediction models on all the tagged sample and used those models to predict the tags for the remaining untagged commit messages. The distribution of different commit messages in all the data is shown in Table 5. These distributions show us that for all the projects and all the classes, a large portion of the students’ commits belong to implementation and fixing bugs. Having very few style-based or documentation and tests commits shows that the students often fix style issues or add documentation and tests for the projects in fewer attempts. This is likely because they can check style errors and code coverage on their local platforms and submit once done, while adding features to their code and getting a functional version of the project that passes all the teaching staff test cases is often challenging and takes many attempts. Teaching staff tests were hidden from students and feedback was only available by committing code to GitHub that was then automatically executed on Jenkins. Students likely made frequent changes to address teaching staff test failures.

5.2 H2. We can automatically classify student teams into Collaborative, Cooperative, or Solo-submit.

In our SME-tagged data, we identified a total of 14 solo working teams, 55 collaborating teams and 28 cooperating teams. We removed five teams from our analysis that had more than two members or only one member contributing either because they were teams of 3 or 1 or because the members changed at some

	Total		2015		2016	
	Count	Ratio	Count	Ratio	Count	Ratio
SME tagged						
Collaborative	55	0.57	18	0.39	37	0.76
Cooperative	28	0.29	18	0.39	10	0.20
Solo-submitting	12	0.14	10	0.22	2	0.04

Table 6: Distribution of the different teamwork styles

	Logistic Regression		
	Collaborative	Cooperative	Solo-submit
F1 Score	0.61	0.67	0.84
Precision	0.51	0.70	0.90
Recall	0.78	0.64	0.78
	Random Forest		
	Collaborative	Cooperative	Solo-submit
F1 Score	0.68	0.78	0.90
Precision	0.63	0.75	0.89
Recall	0.79	0.83	0.92

Table 7: The performance of prediction models for students’ teamwork style

point. The detailed breakdown of the repositories into different styles for each year is shown in Table 6. The performance of the Random Forest classifier and the Logistic Regression with recursive feature elimination is shown in Table 7. As shown in this table, both models had similar performance in predicting the students’ teamwork style, Random Forest performed slightly better, with solo-submit being the easiest to predict and collaborative being the most difficult.

The random forest model worked best with 12 features and the logistic regression worked best with 26. Since random forest performed better at predicting the teamwork style, we analyzed the top features for these random forest models. As these features show, the students’ activities in different parts of the project and their prior individual performance were good predictors for their teamwork. Most of the top 12 features selected by random forest for the collaborative, cooperative, and solo-submit classifiers were specific to each of the teamwork style, but some of the features like the *Average deletion per commit for user 0* were common across styles. The *Percentage of commits for the whole project* for both users were the top features for predicting Solo-submitting, while the *Percentage of commits* in different categories and the *Students’ prior performance* were more predictive for Collaborative and Cooperative. Surprisingly, the *Number of pair-programming activities* were not among the top features, which might be because the students do not always record pair programming in their commit messages.

These prediction models show us that we can identify the students’ teamwork style, especially solo-submitting by using automatically generated features from their commit history and their contributions to the different parts of the project. One might assume that looking at the repositories and the students’ number of commits should be sufficient for identifying solo-submitters. However, as the SMEs noticed, deciding whether both members had significant contributions to the team was challenging and time-consuming, even for experienced TAs. Most of the defined metrics such as the *Amount of implementation commits* or the *Percentage of commits* in a repository can be extracted automatically early in the semester. As a result, using predictive models with these features could help identify the need for early

intervention, for example when teamwork habits indicate that solo-submit may eventually happen in a team.

6. LIMITATIONS AND FUTURE WORK

There are three main limitations to our work. First, our dataset is drawn from a single course. Thus it is possible that the observed results will not generalize to courses with a different team structure or grade breakdown. We do argue however that the analytical methods we chose are general and we plan to evaluate them on different courses in a future study. Second, our classification of the student teams was based solely on their observable online behavior and did not consider offline activities. It is possible that offline behaviors such as students meeting face to face, or exchanging code through other media, might affect our results.

7. CONCLUSION

In this study, we first hypothesized that we could automatically identify students’ activities on different parts of development projects based on the text of their commit messages. We later hypothesized in H2 that we could automatically identify different teamwork styles among students using their online submissions and which parts they belong to. For the first part, we manually tagged 400 commit messages as belonging to different parts of the projects as Implementation, Testing, Debug, Style, Documentation, Merge, and Other. We then used TF-IDF features and a logistic regression to automatically label the remaining commits. To analyze different styles in students’ teamwork, we manually labeled 100 GitHub repositories of student projects in two offerings of a Java introductory course for CS majors as “Collaborative”, “Cooperative”, or “Solo-submit”. We then used several measures based on the students’ activities on GitHub, their prior performance, and whether they chose their teammate to automatically label all the student repositories in these classes. We observed that these models were able to achieve an F1 score of 0.68 or better for different categories, which supported our hypothesis that students’ online activities can identify their teamwork style.

The students in these classes were not graded for their amount of contributions on GitHub. As a result, students were able to split the work among themselves based on their choices and what we observed here was their natural behaviors. This makes the findings in this study more likely to apply to other classes since the students’ teamwork styles were not directed by the course structure.

The findings of this study can be used to analyze which styles of teamwork lead to better performance in classes. Eventually, the findings can help design adaptive support platforms for the instructors to observe a summary of the students’ activities and possible red flags in their behavior such as solo-submitting. The instructors can then plan interventions in a timely manner to help the students to better engage with authentic team projects in the class.

Process based Analysis on Scientific Inquiry Tasks Using Large-scale National Assessment Dataset

Tao Gong, Lan Shuai,
Burcu Arslan, Yang Jiang
Educational Testing Service
tgong@ets.org

ABSTRACT

This paper investigates differences in students having various scores when designing controlled experiments in two types of scientific inquiry tasks (a fair test and an exhaustive test). We measure temporal features of preparation time and execution time, which reflect respectively the process of question understanding and answer planning and that of executing the control-of-variables strategy in answer formulation. We also measure mean execution time per answering event to reflect the efficiency of answering events. Results show that: in the fair test, the full score students showed less execution time than the lowest score ones; in the exhaustive test, the full score students showed more execution time than the lowest score ones; but in both tests, the high-performing students had less mean execution time than the low-performing ones. These results reveal that despite test differences, students who appropriately apply the control-of-variables strategy in these tests are more goal-directed and efficient in planning and executing response strategies than those who fail to do so. This study provides process-based features and large-scale evidence of scientific inquiry practice in educational assessment.

Keywords

Control-of-variables strategy, preparation time, execution time

1. INTRODUCTION

Scientific inquiry refers to the activities by which students develop knowledge of scientific ideas and understand how to investigate the natural world in a scientific way [1]. In STEM education, scientific inquiry skills have been emphasized as a key goal of scientific literacy [2,3], and scientists and science educators have advocated teaching science as inquiry [4–8]. Among scientific inquiry activities (see [6] for overview), *planning*, *designing*, and *carrying out investigations* have long become a principal focus of children's and youngsters' scientific inquiry practices [9,10]. Many studies aim to investigate, based primarily on response data, how students design controlled experiments by constructing related conditions for comparison.

Fair tests and exhaustive tests have been widely adopted to examine how students plan, design, and carry out controlled experiments. A *fair test* (see an example in Sec. 2.2) refers to a controlled investigation carried out to answer a scientific question

about the effect of a target variable. To control for confounding factors and be scientifically sound, students are supposed to apply a *control-of-variables strategy* (CVS) [9,11] to ensure that: (a) all the other variable(s) are kept constant; and (b) only the variable(s) under investigation is changed across conditions for comparison. Only in such a fair setting, the effect of the target variable(s) can be explicitly observed, since the other variables remain constant across conditions. Students can complete the task by choosing, among a large number of possible combinations of variables, one or a few conditions that meet the fair test requirement.

An *exhaustive test* (a.k.a. combinatorial test, [12,13]) (see an example in Sec. 2.3) requires constructing, physically or mentally, all possible combinations of given variables to address inquiry on which conditions could cause a specific outcome. Like fair tests, students in exhaustive tests also need to control target variables to construct combinations, but the number of possible combinations is generally smaller than that in fair tests. In exhaustive tests, students are asked to enumerate all combinations; in fair tests, students only need to select one (or a few) condition that meet the requirement. In this sense, exhaustive tests require more cognitive resources especially in situations with not easily foreseen combinations. How to conduct an exhaustive test is taught and learned late in science education, and items assessing such skill often lie in the 8th, 12th, or higher-grade assessments [3].

CVS is required in both types of tests. Among other types of procedural knowledge, or “process skills”, CVS is deemed central to early science instruction [14]. Existing research shows that children, adolescents, and adults with low scientific inquiry expertise tend to have difficulty in applying CVS [9,10,15]. However, due to lacking measures on processes of scientific inquiry, existing studies focus primarily on students' responses.

In modern digitally-based assessment programs (e.g., National Assessment of Educational Progress (NAEP)), technology-enhanced (TE) items have been used to study scientific inquiry practice. The interactive nature of such items allows recording not only final submitted answers, but also the process whereby students formulate their answers via a series of drag-and-drop, (de)selection, or correction actions. Obtained process data can gather additional evidence on what students do during inquiry [16–18]. TE items have now touched upon many disciplines, including math, science, and social science [18–21], and process data obtained have covered not only observable behaviors of test-takers in problem solving but also frequencies and durations of such actions, both contributing to illustrating the mastery phases in scientific inquiry and response strategies of students [22–25]. In addition, process-based analyses help discover the aspects where students of different scores differ, and lead to better understanding of the cognitive framework of scientific inquiry.

Tao Gong, Lan Shuai, Burcu Arslan and Yang Jiang "Using Process Data to Evaluate Scientific Inquiry Practice in Technology-Enhanced Assessment" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 417 - 423

Rather than concrete events recorded in obtained process data of TE items, the time needed for different stages of scientific inquiry has been undervalued in recent research of scientific inquiry or problem solving [26]. Temporal information can reveal different stages of problem solving, clarify performance patterns of students with different levels of problem solving competency, and allow inferring something about the cognitive processes occurring at various phases of problem solving.

Noting these, this study aims to investigate the scientific inquiry practice, to be specific, the practice of designing controlled experiments by applying the CVS in fair and exhaustive tests. By evaluating relations between defined process-based, temporal measures and students' performance gauged by scores, we aim to address the following two research questions:

- (a) What are the process-based characteristics of the high-/low-performing (indicated by different scores) students in the tests?
- (b) Are these process-based characteristics consistent across the fair and exhaustive tests?

Answers to these questions can benefit the general discussions on scientific inquiry practice, especially whether the CSV strategy manifest differently across various types of inquiry tasks. They also provide actionable feedback to teaching and learning the skills required in scientific inquiry tasks. Moreover, this study enriches the literature of using process data and derived features to address theoretical issues in educational assessment.

In the rest of the paper, we describe the NAEP science fair test and exhaustive test used in this study, define the process-based measures, and describe the analysis plan. Then, we report the results, discuss the research questions accordingly, and conclude the study by highlighting theoretical or operational applications of process-based analyses in education and psychology research.

2. METHODS AND MATERIALS

2.1 NAEP Science Tasks

Our study uses the 2018 NAEP science pilot tasks. NAEP is a congressionally mandated, nationwide digital assessment project administered by the National Center for Education Statistics (NCES) in the Institute of Education Sciences of the U.S. Department of Education. NAEP provides large-scale, regular assessments on many disciplines (e.g., math, reading, writing, science, etc.). All the assessments are designed and updated by content specialists, education experts, and teachers from around the U.S. Participants of the tests are grades 4 (~9-year-olds), 8 (~13-year-olds) and 12 (~17-year-olds) students. Along with the assessment, survey data of students, teachers, and schools are gathered, covering students' demographical information (gender and ethnicity), special programs, self-evaluation of performance, etc. NAEP has now become one of the largest and most important national assessments of what U.S. students know and can do.

The 2018 assessment was conducted by the NAEP field staff, who went into schools across the nation to administer tasks on students from the NAEP sample. The science tasks were administered on NAEP-provided tablets with an attached keyboard and earbuds. Students had 60 minutes to complete the questions in the given task. Tutorials and surveys were given throughout the test.

A total of 32 science tasks were designed for the 2018 NAEP pilot test, some of which were administered on grades 4, 8, and 12 students. Our study focuses on a fair test and an exhaustive test,

which were administered respectively on grade 8 and 12 students. This choice was due to three considerations. First, lower grade students have not been taught how to solve both types of tests, so we avoid tasks administered on grade 4 students. Second, since fair tests were administered mostly on grade 4 and 8 students but exhaustive tests were administered mostly on grade 12 students, we could not select fair tests and exhaustive tests administered on students of the same grade. Third, to properly answer the two chosen tests, students needed to submit similar numbers of distinct answers, which avoided possible interference from cognitive load in students' answer formulation process.

Due to the privacy and secure nature of the NAEP data, we use conceptually equivalent tasks (*cover tasks*) to disguise the content and context of the real tasks. Cover tasks have similar underlying structures and require similar cognitive processes to solve.

2.2 Fair Test, Scoring Rubric, Students

This test came from an earth and space science task. Its cover test is as follows (see Figure 1). A city near a mountain suffers from north winds each year. Its government plans to test the wind-blocking power of three types of trees, which can be planted at the north side of the mountain. After simple instructions of the task, in the fair test scene of the task, students are asked to drag each type of trees and drop them at one of the four virtual mountains resembling the real one near the city. Students can drop the trees at the foot (low), side (medium), or peak (high) of the north side of a mountain. Each mountain holds at most one type of trees, and each type can only be planted at one mount. Students can move trees from one position/mountain to another. After selecting the locations of the three types of trees, students can click on the on-screen "Submit" button to trigger the experiment, and the wind speeds before and after passing over the mountains are shown on the screen. By default, one mountain is left without any tree.

There are two types of variables in this fair test: tree type and tree position on mountain. To illustrate the effect of trees, students must control the positions of the trees to be identical across conditions (mountains). There are in principle $3 \times 3 \times 3 \times P(4,3) = 648$ choices for students to plant the trees, among which $3 \times P(4,3) = 72$ choices meet the fair test requirement.

Figure 1. Example answers in the fair test. "Low", "Medium", "High" denote positions (foot, side, peak) of trees in the north side of the mountain. "None" means no tree planted. In (a), the first "Low" indicates that one type of trees are planted at the foot of the mountain, the second and third "Low" indicate that the other types of trees are planted on the second and third mountains, and "None" means no trees on the fourth mountain. The scoring rubric ignores tree types and the mountain without trees, the submitted answer can thus be denoted by the positions of trees in three mountains.

Table 1 shows the scoring rubric of this test. The rubric ignores tree type, since students cannot put the same type of trees in two mountains or two positions of one mountain. It also ignores the mountain without trees (“None”), since this is a default condition of the test; no matter how to answer the test, one mountain must be left without trees. A complete comparison to show the effects of trees requires the condition without trees, but in this test, students are not required to set up this condition. The rubric focuses on the target variable of tree positions across mountains. Answers meeting the fair test requirement receive a full score (3), those partially meeting the requirement get a partial score (2), and those not meeting the requirement have the lowest score (1).

Table 1. Scoring rubric of the fair test.

Score	Rubric
3	Choices of trees have the same positions on three mountains (e.g., Low; Low; Low in Figure 1(a))
2	Two types of trees are on the same positions of mountains (e.g., Medium; High; High in Figure 1(b))
1	Positions of the three types of trees on mountains are all distinct (e.g., Low; High; Medium in Figure 1(c))

This task was administered to 1,657 (825 females) grade 8 students. The response and process data of 1,607 (800 females) students were recorded in the fair test for analyses. Fifty-one students, due to various reasons, quit before reaching the fair test.

2.3 Exhaustive Test, Scoring Rubric, Students

This test came from a life science task. Its cover test is as follows. Farmers attempt to cultivate flowers with a special color in a natural way (without using any fertilizers) or using two types of fertilizers. After simple instructions of the task, students are asked to design an experiment to show which way has the highest probability to induce the target color. They can set up a condition by selecting (or not) any (or both) type of the fertilizers. After setting up a condition, they can click on the on-screen “Save” button to save the condition. They can also click on a saved condition and click on the “Delete” button to remove it. After setting up and saving many conditions, students can click on the “Submit” button to submit saved conditions as final answers.

This is a typical exhaustive test with four possible combinations of the variables (see Figure 2). The conditions no fertilizer (Figure 2(a)) and both fertilizers (Figure 2(d)) are not easily foreseen.

Figure 2. All combinations in the exhaustive test: (a) None; (b): A; (c): B; (d): A + B.

Table 2 shows the scoring rubric of the test. It has four scales, among which partially high (3) and partially low (2) are classified by submitted saved conditions, especially whether they include

the not-easily foreseen conditions. Whether the rubric reasonably classifies students’ skill levels is not the focus of this paper.

This task was administered to 2,869 (1,360 females) grade 12 students. The response and process data of 2,726 (1,285 females) students were recorded in the exhaustive test for the analyses. Due to various reasons (e.g., early quitting or glitches in data capture), the process data of 173 students were missing.

Table 2. Scoring rubric of the exhaustive test.

Score	Rubric
4	Saved conditions cover all four conditions in Figure 2
3	Saved conditions do not include the condition of Figure 2(a), OR do not include the condition of Figure 2(b) or Figure 2(c)
2	Saved conditions do not include the condition of Figure 2(d), OR do not include the conditions of Figure 2(b) or Figure 2(c), OR do not include both the conditions of Figure 2(a) and Figure 2(d)
1	Saved conditions do not match the above cases

2.4 Process-Based Measures

The NAEP digital assessment system can record students’ process data in these interactive TE items. Such data consisted of a list of activity logs plus their time stamps. Activities included user events (e.g., drag-and-drop, save, delete, or correct, etc.) and system events (e.g., play instructions or video clips). They allow reconstructing submitted answers, tracing sequences of students’ drag-and-drop or saving/deletion/correction actions, and durations of these activities. Based on such data, we propose and measure three temporal measures, namely preparation time, execution time, and mean execution time per answering event.

Preparation time (PT) is defined as the duration between students enter the test scene and make their first answer-related event, such as drag-and-drop one type of trees, select a fertilizer, or save a condition without any fertilizers. Before the test scenes, students were given instructions and practice trials on how to set up answers in the test scenes. Therefore, PT does not involve the time students spent on getting familiar with the system. PT reflects the time for students to read and understand instructions, as well as think and get ready to formulate their answers.

Execution time (ET) is defined as the duration between students’ first and last answer-related events. The ending time point of ET was not when students clicked on the submission button. This is because we do not know exactly whether students reviewed their answers after making their last drag-and-drop or selection event before submission. If they did review and made corrections, the measure can certainly capture such reviewing event; if they did not make any changes, it is unclear whether the time between the last answer-related event and the submission event was spent on reviewing. Many students actually clicked on the “Submit” button immediately after the last answer-related event.

ET is the sum of the durations of different numbers of answer related events. In the fair test, such events include dragging and dropping a type of trees to a mountain or moving one from one mountain to another; in the exhaustive test, such events include selecting one or two fertilizers, or saving a condition or cancelling a saved one. Students having different performances may put different efforts when conducting these events, and different tasks may require different numbers of events to formulate answers, which already lead to different ET. Noting these, we also calculate

the *mean execution time per answering event* (MET). MET is operationalized as the execution time divided by the number of answering events. ET reflects the total efforts made by students to construct answers, including setting up, revising or (possibly) reviewing their choices, whereas MET reflects the average effort made to construct their answers, and it controls the effect induced by different numbers of events.

Apart from temporal measures, one can also measure the numbers of answer related events made by students during the answering process. However, for students who conducted the same number of answering events, this count-based measure cannot clarify how much effort each event costs to these students; more events may not always require more efforts, since an efficient test-taker can conduct many events in a short period of time; and more events alone cannot predict performance in different tests, since some of the events could be answer revisions, which simply indicate low efficiency. The temporal measures defined in our study avoid these confusions and are more informative of students' degrees of efficiency in designing controlled experiments in those tasks.

2.5 Analyses

For each dataset, we take a 98% winsorization estimation [27] to remove spurious outliers. We also remove the missing values.

We conduct two types of analyses. First, we check how many students appropriately applied the required CVS in the tests based on score distributions and illustrate the frequent (top 10) correct or incorrect submitted answers. Second, treating score as a ranked variable, we conduct the Kruskal-Wallis test [28], a non-parametric version of ANOVA test, to compare students' scores and the three measures across score groups. If the omnibus test produces a significant p -value, we conduct the Wilcoxon signed-rank test on pair-wised score groups to clarify which two groups have different population means of the measures. This test is also non-parametric. These two statistical tests provide direct evidence on the relation between students' performance (scores) and the process-based measures. The tests are implemented using the `kruskal.test` and `wilcox.test` functions in the *stats* package in R 3.6.1 [29]. For each task, there are three Kruskal-Wallis tests respectively on three measures, accordingly, the critical p value for identifying significance is set to $.05/3 \approx .0167$.

3. RESULTS

3.1 Fair Test

In this test, 41.4% of the students had the lowest score (1), and only 29.5% properly applied the CVS and got the full score (3). The rest (29.1%) received a partial score (2).

Figure 3 shows the top 10 frequent answers submitted by students. It shows that "Low; Low; Low" is the most frequent correct answer, but other correct answers like "Medium; Medium; Medium" and "High; High; High" are less so. In addition, "Low; Medium; High" is the most common wrong answer. Its variations, such as "High; Medium; Low" or "Low; High; Medium", are also frequent, but all of them receive the lowest score (1) (see Table 1). Answers receiving a partial score (2) (e.g., "Medium; Low; Medium") are less frequent, compared to other types of answers. These results indicate that over 70% of students did not properly apply the CVS strategy in this scientific inquiry task.

Table 3 shows the means and standard errors of the process-based measures in each score group. The Kruskal-Wallis tests report significant differences in PT ($\chi^2 = 12.2$, $df = 2$, $p = .002$), ET ($\chi^2 =$

89.916, $df = 2$, $p < .001$), and MET ($\chi^2 = 64.776$, $df = 2$, $p < .001$) between score groups. Table 4 shows the Wilcoxon signed-rank tests results. It reveals that the full score students had significantly shorter PTs, ETs, and METs than the lowest and partial score students, but these measures were not significantly different between the lowest and partial score students.

Figure 3. Top 10 frequent answers in the fair test. Numbers on top of bars are numbers of students and those inside brackets are proportions of students.

Table 3. PT, ET and MET across score groups. Numbers (in seconds) outside brackets are means and those inside are standard errors.

Score	PT	ET	MET
1	85.571 (1.166)	41.330 (1.098)	5.125 (.091)
2	85.154 (1.407)	38.807 (1.216)	4.958 (.103)
3	79.745 (1.172)	29.082 (1.081)	4.138 (.090)

Table 4. Wilcoxon signed-rank test results in the fair test. "1" to "3" in the first column denote score groups. Values outside brackets are test statistics, and those inside are p values. Significant results are marked in bold.

	PT	ET	MET
1v2	158942 (.527)	163023 (.016)	158766 (.548)
1v3	176639 (.001)	2038350.5 (.001)	199945.5 (.001)
2v3	120966.5 (.014)	139637.5 (.001)	136592.5 (.001)

3.2 Exhaustive Test

In this test, 25.2% of the students received the lowest score (1), and 33.9% properly applied the CVS strategy and received the full score (4). The rest received the partially high (3) (34.1%) and partially low (2) (6.8%) scores.

Figure 4 shows the top 10 frequent answers, among which "A; B; A + B; None" and its variations "A; A + B; B; None" and "A + B; A; B; None" receive the full score (4), but they are not frequent compared to the answers "A + B", "B", "A", and "None", which are among the most frequent answers and receive the lowest score (1) (see Table 2). The answers having partially high (e.g., "A; A + B; None") or low (e.g., "A; A + B") scores are less frequent. These results show that many students did not have the required scientific inquiry skill.

Table 5 shows the means and standard errors of the process-based measures in each score group. The Kruskal-Wallis test report significant differences in PT ($\chi^2 = 127.69$, $df = 3$, $p < .001$), ET ($\chi^2 = 332.88$, $df = 3$, $p < .001$), and MET ($\chi^2 = 238.93$, $df = 3$, $p < .001$) between the score groups. Table 6 shows the Wilcoxon signed-rank tests results. It reveals that the lowest score students had significantly longer PTs than the students from other score groups. Unlike the fair tests, the lowest score students had significantly shorter ETs than the full and partial score students. Like the fair tests, the lowest score students had significantly longer METs than the full score students.

Figure 4. Top 10 frequent answers in the exhaustive test. Numbers on top of bars are numbers of students and those inside brackets are proportions of students.

Table 5. PT, ET, and MET across score groups. Numbers (in seconds) outside brackets are means and those inside are standard errors.

Score	PT	ET	MET
1	9.056 (.325)	24.949 (.922)	5.502 (.144)
2	6.797 (.439)	41.623 (1.804)	3.520 (.113)
3	7.105 (.207)	31.700 (.715)	3.899 (.070)
4	5.714 (.172)	42.523 (.763)	3.140 (.051)

Table 6. Wilcoxon signed-rank test results in the exhaustive test. “1” to “4” in the first column denote score groups. Values outside brackets are the test statistics, and those inside are p values. Significant results are marked in bold.

	PT	ET	MET
1v2	75018.0 (<.001)	29065 (<.001)	83948 (<.001)
1v3	372475.5 (<.001)	215673.5 (<.001)	400288.5 (<.001)
1v4	422941.5 (<.001)	128978.5 (<.001)	458813.5 (<.001)
2v3	84443.5 (.693)	11656 (<.001)	80219.5 (.147)
2v4	98433.5 (<.005)	81207 (.284)	100851 (<.001)
3v4	501936.5 (<.001)	274362.5 (<.001)	531023.5 (<.001)

4. DISCUSSIONS

Based on two NAEP science tasks (a fair test and an exhaustive test) and three process-based temporal features, we dig out, from both response and process data, the differences and similarities between the high-/low-performing students in those two typical types of scientific inquiry practice.

As for response, the score distributions illustrate that many (over 70%) grade 8 or 12 students failed to properly apply the control-of-variables strategy in the fair and exhaustive tests, consistent with the previous literature [9]. In addition, in the fair test (see Figure 3), the most commonly wrong strategy is to vary both variables’ levels at the same time, e.g., “Low; Medium; High” and its variations. This is also shown in previous observations [17]. In the exhaustive test (see Figure 4), the most commonly wrong strategy is to save only one of the four possible conditions as in Figure 2. This indicates that the low-performing students probably did not have the intention or the capability to design a controlled experiment but simply guessed an answer.

As for process, rather than specific actions or sequences of drag-and-drop actions as in recent studies on TE items [30], our study defines temporal features and adopts non-parametric statistical tests on these stage-level features to reveal quantitative differences between the high- and low-performing students.

The statistical tests collectively show that: in terms of preparation, the full score students spent less time before making their first answering related activity in both the fair and exhaustive tests, which are consistent with other studies [30]. Longer preparation time in the lowest score students shows that such low-performing students might have difficulty in quickly grasping the instructions or need more time to think before taking any action, whereas the high-performing students could efficiently grasp the instructions and foresee the required conditions. These results suggest that the different performances between the full and lowest score students have already manifested at the early stage of scientific inquiry practice, where no answer is formulated. In other words, whether a student can appropriately apply the control-of-variable strategy in a fair task could be highly correlated with whether he or she can efficiently grasp the instruction at the beginning of the task.

In terms of execution time, there exist differences between the fair and exhaustive tests. In the fair test, the lowest score students spent longer time on conducting the drag-and-drop actions to construct answers. As shown in Figure 3, their submitted answers after such a long execution time still failed to meet the fair test requirements. This echoes the fact that these students did not follow the instructions nor get well prepared for the fair tests. To be specific, in the fair test, the minimum number of events to construct an answer was three (dragging and dropping each type of trees respectively to the same or different locations of three mountains). Two possible situations lead to longer execution time in the lowest score students: they conducted many revisions to their early choices, or spent more time on conducting each activity, indicating their hesitation or uncertainty about their choices, or more time needed to come up with a solution due to a lack of relevant domain knowledge. Here, the results of mean execution time per answering event (see Table 4) reveal that no matter how many revisions they conducted, on average, the lowest score students spent more time on setting up each of their answers than the full score students; i.e., the full score students were more efficient than others.

In the exhaustive test, constructing all possible conditions is not trivial and requires more resources and related events. As shown in Table 5, the lowest score students spent shorter time in constructing or revising their saved conditions, whereas the full score students spent longer time in doing so. As in Figure 4, the lowest score students (and those having partial scores) did not save enough conditions, but the full score students submitted each

of the possible conditions as required by the test. Therefore, the longer execution time of the full score students reflects the fact that these high-performing students had endeavored to set up all required conditions before the final submission. By contrast, the shorter execution time of the lowest score (and partial score) students indicates that: (a) these low-performing students did not spend much time on exploring possible conditions but completed the test by submitting lack-of-thinking results, indicating their low motivation or lack of engagement in problem solving; or (b) throughout the test, they might not realize that they needed to save and submit all possible conditions, so they simply submitted one condition and left the test. Both cases are consistent with the response data of frequent wrong answers submitted (see Figure 4), but they point to different causes of failing the test.

Since the numbers of conditions saved are different across score groups, comparing the execution time, which is the sum of the duration of different numbers of actions, is not enough to reflect whether the efficiency of high- or low-performing students is similar. We need to further compare the mean execution time per answering event. The full score students spent less time (see Table 6) on conducting each answering related action than the low-performing students. This implies that although the full score students conducted more actions, they were more efficient, by putting less effort on each action, than the lowest score students (and those having partial scores). In this sense, the results in the two tests are consistent: the students who properly apply the control-of-variable strategies show more goal-directed and efficient behaviors [30] than those who failed to do so.

The contrasting results of execution time between the fair and exhaustive tests reveal the differences between the two types of scientific inquiry practice. Although both tests require controlling variables under investigation, the nature of control is different, so are the required cognitive resources to properly complete the tests. In the fair test, to study the effect of a target variable (tree type, see Figure 1), students need to keep the other variable (tree position) unchanged. In the exhaustive test, students need to combine different values (use or not use, see Figure 2) of the variables (fertilizers A and B) to set up a set of conditions for comparison. Properly completing this test requires mentally constructing the conditions not easily foreseen and spending time and energy in thinking and setting up each possible condition, thus requiring more cognitive resources than the fair test, the latter of which only requires adjusting the target variable and holding the other one(s) constant. These results indicate that the same control-of-variables strategy manifests differently in different scientific inquiry practices. Systematic teaching and learning of this strategy require task-specific training in different situations.

All the results reveal the aspects in which high-performing students excel low-performing ones, including: (a) grasping instructions, (b) extracting requirements, and (c) constructing answers. Compared to high-performing students, low-performing students had lower efficiency in grasping necessary knowledge and applying required strategies in the tests. As a consequence, in the fair test, low-performing students struggled in selecting and revising answers, and ended up submitting wrong answers; and in the exhaustive test, they failed to envision all possible conditions, and failed to construct enough conditions as the final answers.

The above discussions focus primarily on statistical differences between the full and lowest score students. This is because that our statistical analyses report consistent results between the two

score groups. However, results are not consistent when partial score groups are involved. Such inconsistency could be due to several reasons. First, some partial score groups contained fewer students than the other two groups. Second, according to the scoring rubrics, the response difference between the full (or the lowest) score and a partial score is smaller than that between the full and lowest scores, which may cause smaller difference in answering events and/or their durations. Both factors reduced the statistical power of the analyses. Third, lacking empirical basis, the predefined score rubrics might not clearly differentiate students having different levels of problem solving competency. This issue is beyond the scope of the current study. Nonetheless, such inconsistency calls for statistically more powerful process-based features to reveal the differences between students having good and poor performances in science inquiry practice and understand how they apply required skills in such practice.

5. CONCLUSIONS

This study makes use of three process-based, temporal measures to analyze how students conduct scientific inquiry in practice. We identify both the global (e.g., durations of thinking, and total duration of execution) differences and local (e.g., execution efficiency) consistency between students who can appropriately apply the control-of-variables strategies in scientific inquiry practice and those who fail to do so. The findings provide new evidence to the general discussions of the relations among individual capacity (e.g., control-of-variables strategy), nature of test (e.g., fair or exhaustive test), problem-solving process (e.g., duration and efficiency of activities), and assessment performance (e.g., submitted answers and scores). The process-based features have proven values in revealing performance differences in the fair and exhaustive tests. Analysis results based on these measures reveal the aspects or stages during the problem-solving process in which teachers can provide guidance or students can self-improve to teach the required inquiry skills or properly apply them, thus improving students' performances in science inquiry practice.

ABSTRACT

Learning curves are an important tool in cognitive diagnostics modeling to help assess how well students acquire new skills, and to refine and improve knowledge component models. Learning curves are typically obtained from a model estimated on real data obtained from a finite, and usually limited, sample of students. As a consequence, there is some uncertainty associated with estimating the model from that sample, and a risk that the inferences made using learning curves derived from the estimated model are over-confident one way or another. Based on previous work modeling the uncertainty on Additive Factors Model parameters, we derive a principled way to quantify the confidence in learning curves associated with each knowledge component. We show that our approach leads to relatively tight bounds on the learning curves, much tighter than a naive approach relying only on parameter uncertainty. This also reveals a disparity across knowledge components regarding how confident one can be in how well these skills are mastered.

Keywords

Learning Curves, Additive Factors Modeling, Knowledge Cognitive Diagnostics Model

1. INTRODUCTION

Learning curves are a crucial tool for cognitive diagnostics modeling. They help build relevant competency frameworks to accurately measure learners skills and to give them meaningful guidance and feedback in intelligent tutoring systems (ITSs). More precisely, learning curves measure the rate at which students, or simulated artefacts [22], acquire competencies. This allows to evaluate the suitability of a competency framework (aka *Q-matrix*) and a principled comparison of different learning systems. Learning curves are “graphs that plots performance on a task versus the number of opportunities to practice” [17]. In the educational field, learning curves usually take as learning performance metric the error rate (or equivalently success rate) when applying

an individual skill or a set of skills. They were empirically found to follow a “power law of practice” [18], which means that the error rate over time decreases roughly linearly with the logarithm of the number of practice trials taken (aka *opportunities*). Comparing ITSs or sections of ITS can be done by considering the steepness of the curve: A steeper curve indicates a faster acquisition of the skills practiced [17].

However, tracking the performance of skills learned in a multidimensional learning environment can be difficult, as those environments combine different set of skills evaluated together. In such situations, some cognitive diagnostic models can be useful to compare learning systems but also to understand the learning mechanisms at play [10]. The Additive Factors Model (AFM) [1], a well known cognitive diagnostics model, does this by assuming that each necessary skill in an item comes with a skill-specific additive contribution towards the probability of success on the item. Fitted AFM parameters can also be used to draw learning curves that compensate for the *attrition bias* [9]: Over time, fewer learners tend to practice some items because many of them have learned the skill, and the curves tend to quickly degenerate, impacting the estimates of the slopes and the diagnostics of how much learning has occurred. In addition, when learning curves are drawn directly from AFM parameters, the validity of the inferences that can be made will depend greatly on the reliability of the parameters values, and ultimately on the quality of the fitted data. More precisely, fitted parameter values tend to compensate for noise, missing values (e.g. due to *attrition*) or mis-specified competency models. Rupp and Templin [21] showed for instance how the fitted values of model parameters in DINA [11] would inflate when fitted with purposely erroneous Q-matrices. We can expect a similar impact with any model using Q-matrices, including AFM, a situation made worse by the fact that, in reality, perfect Q-matrices are difficult to identify [5], even when they are retro-engineered from performance data [19]. This motivates the necessity to estimate not only parameter values, but also the statistical confidence on those values, and take into account this uncertainty in any model interpretation, whether based on those values or on the associated learning curves.

Previous work investigated the estimation of standard errors on DINA [20] or AFM [7] parameters, and showed how it could impact learning curves shape and ultimately AFM interpretability and usefulness [15]. Assuming independence across parameters, they produced bounds on learning curves

Cyril Goutte and Guillaume Durand "Confident Learning Curves in Additive Factor Modeling" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 424 - 430

using standard confidence intervals on parameter values. However, in practice, the AFM skills parameters (Section 2) are clearly not independent. In this contribution, we show how we can take into account the structure of the covariance between the AFM parameters in order to better model and control the uncertainty on those parameters. We describe a technique for generating confidence intervals on the learning curves using a sampling approach. We illustrate how this works on several competency models from a well-known dataset obtained from a geometry tutoring course, and we show how it allows us to compare how different competency models may model the same skills with different confidence.

In the following Section, we quickly describe the AFM model and introduce our method for obtaining more adequate estimates of the confidence intervals on the learning curves. Section 3 quickly describes the well known EDM dataset that we experiment with in Section 4. Section 5 discusses the results and their impact before we conclude.

2. METHOD

The Additive Factors Model (AFM) introduced by Cen et al. [1, 3] is used in the PSLC-Datashop [12] in order to evaluate domain models. It models the probability of success of a student i on item j using user and skill specific parameters:

$$P(Y_{ij} = 1 | \alpha_i, \beta, \gamma) = \sigma \left(\alpha_i + \sum_{k=1}^K \beta_k q_{jk} + \sum_{k=1}^K \gamma_k q_{jk} t_{ik} \right) \quad (1)$$

with $\sigma(x) = 1/(1 + e^{-x})$ the logistic function, and

α_i is the *proficiency* of student i ,
 β_k is the *easiness* of skill $k = 1 \dots K$,
 γ_k is the *learning rate* for skill k ,
 $\mathbf{Q} = [q_{jk}]$ is the $J \times K$ *Q-matrix*, representing the cognitive model mapping items to skills,
 t_{ik} is the number of times student i has practiced skill k (on any item).

Parameters $\theta = (\alpha, \beta, \gamma)$ are estimated by maximizing the (penalized) likelihood of the model over observed student outcomes (see e.g. [6]). One attractive feature of AFM is that it easily provides performance curves showing how students acquire skills. Among the different types of learning curves that can be derived from AFM [9, 8], we focus on the data- and student-independent *idealized learning curve* [8],¹ that simply traces the probability of error for an idealized student with $\alpha = 0$ proficiency, on an item with a single skill k :

$$LC_k(t) = 1 - P(Y = 1 | \alpha = 0, \beta, \gamma) = \sigma(\beta_k + \gamma_k t). \quad (2)$$

Learning curves are typically computed with the maximum penalized likelihood parameters $\hat{\theta} = (\hat{\alpha}, \hat{\beta}, \hat{\gamma})$. As noted for example by Philipp et al. [20] and derived for AFM by Durand et al. [7], one can also estimate the uncertainty on $(\hat{\alpha}, \hat{\beta}, \hat{\gamma})$, in the form of standard errors. This is relatively straightforward as the covariance matrix on parameter estimates is asymptotically equal to the inverse of the information matrix, $\text{Cov}(\hat{\theta}) = \mathcal{I}_{\hat{\theta}}^{-1}$. The information matrix $\mathcal{I}_{\hat{\theta}}$ can

¹aka Individual Learning Curve in [9].

 Compute learning curve $LC_k^{(i)}(t)$ for target skill k

until N simulations;

For each opportunity t , compute confidence interval $[\ell_k(t), u_k(t)]$ using relevant quantiles² of $\{LC_k^{(i)}(t)\}$.

be estimated from first or second order derivatives of the cost function [20, eq. 3, 4]. This also provides a key to quantifying the uncertainty on the learning curves. Using the fact that parameters are (asymptotically) normally distributed around $\hat{\theta}$ with the known covariance matrix $\text{Cov}(\hat{\theta})$ [7], we can sample sets of parameters from that multivariate Gaussian distribution, compute the learning curve for each set of parameters, then empirically estimate the error bars on the learning curve through the relevant quantile statistics, as outlined in Algorithm 1.

Although Algorithm 1 focuses on producing error bars on the learning curves, we can also use the simulated sample to evaluate the stability of the entire learning curve, using for example the average standard deviation across opportunities:

$$\bar{\sigma}_k = \frac{1}{T} \sum_{t=1}^T \text{st.dev.}\{LC_k^{(i)}(t)\}$$

Lower $\bar{\sigma}_k$ indicate that the sampled learning curves are closer together, thus the learning curve is more stable.

3. DATA

For our experiments, we used the “Geometry Area (1996-97)”, a public dataset from DataShop [12]. This dataset contains 6778 observations of the performance obtained by 59 students completing 139 unique items from the “area unit” of the Geometry Cognitive Tutor course (school year 1996-1997). This dataset has been extensively used [1, 2, 7, 13, 14]. We selected three knowledge component (KC) models:

- hLFASearchAICWholeModel3arith0 (referred to simply as **arith** below),
- hLFASearchModel1-context (**context** below),
- Original (**orig** below).

These KC models were selected for their reasonable numbers of skills and observations but also because they have distinctive goodness of fit metrics, suggesting that they are high-performing KC models. Table 1 shows that the best predictive model would be **arith**. The number of skills (KCs) seems to have limited impact on the goodness of fit metrics.

²For example, the 95% confidence interval is obtained as

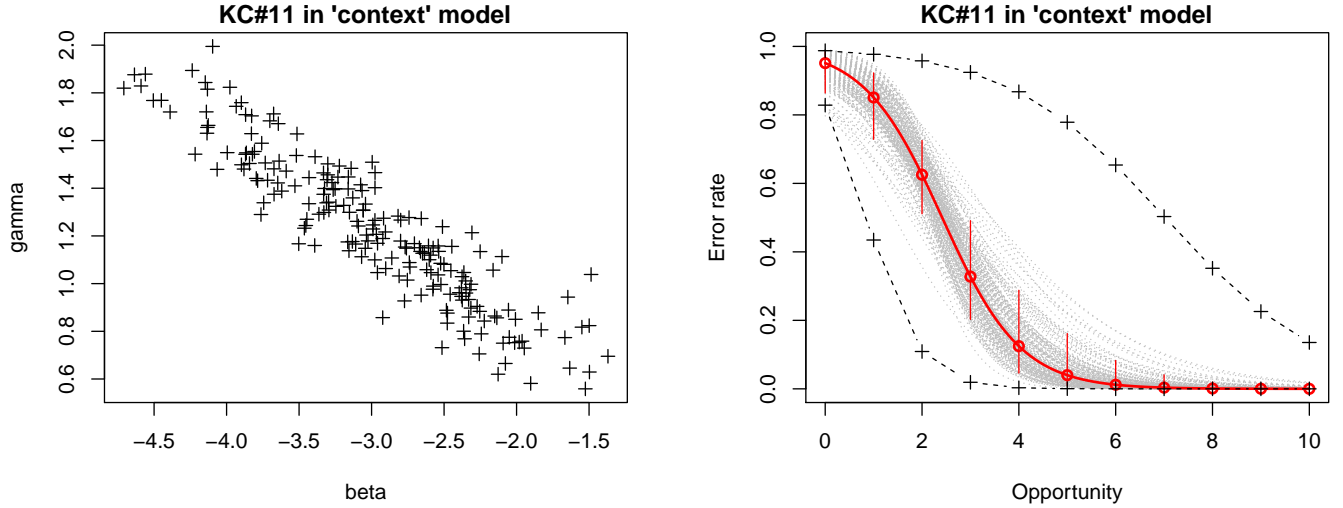

Figure 1: Left: Sampled β and γ for KC#11 of the context model. Right: Corresponding learning curves (in light gray); the LC given by the AFM model is in red, with 95% confidence intervals at opportunities up to 10 shown as red vertical bars. The 95% CI from [7] is indicated in black crosses for comparison.

Table 1: Characteristics and predictive quality of the KC models, as computed by PSLC-Datashop.

Name	KCs	Stud.	#Obs.	AIC	BIC	RMSE
arith	18	59	5104	4948	5569	.397
context	12	59	5104	5030	5573	.399
orig	15	59	5104	5180	5762	.407

Another motivation for choosing these KC models is their skills sharing as some skills have an identical mapping to items in another model, allowing to compare the stability of the same skill across KC models.

4. EXPERIMENTS

In this section, we first illustrate how we derive error bars on the learning curve for a specific KC, then show results for an entire KC model, and finally we compare the stability of learning curves for equivalent skills in different KC models.

4.1 Illustration

We focus on KC#11 (*equi-tri-height-from-base/side*) from KC-model *context*. This is a relatively hard ($\beta = -2.97$) skill, but with quick learning ($\gamma = 1.23$). Figure 1 (left) shows the values of β_{11} and γ_{11} that were sampled by Algorithm 1 for this KC. As seen in the plot, the marginal uncertainty on β_{11} and γ_{11} is quite high (from -4.5 to -1.5 for β_{11}), but they are also very correlated: samples with higher *easiness* have lower *learning rate*.

Each of the points in Fig. 1 (left) is translated into a corresponding learning curve (Eq. 2) in dotted light gray in Fig. 1 (right). Due to the correlation noted before, we can see that the sampled learning curves are actually fairly stable, compared to what extremes of the distributions of β_{11} and γ_{11} would suggest (see dashed lines with crosses in Fig. 1,

$[q_{2.5}, q_{97.5}]$, where q_ϵ is such that $\epsilon\%$ of the sample is below q_ϵ and $(100 - \epsilon)\%$ is above.

which replicates Fig. 4 from [7]). The red curve in Figure 1 (right) is the learning curve computed from the AFM solution, with 95% confidence intervals obtained from the sample at each opportunity indicated as red bars. We see that although there is some uncertainty around the steep part of the curve, the learning curve is well-controlled and easy to diagnose, indicating that the skill is completely acquired after around 5 opportunities.

4.2 Application to KC models

We now show how we can generate learning curves with confidence intervals for a full KC model. The process illustrated above is applied to each KC, producing one learning curve with confidence bounds. For improved readability, we show the results on KC-model *context*, which has the smallest number of KCs among our three models.

Figure 2 shows the learning curves for the twelve knowledge components. We can see that most learning curves are well-controlled. The average standard deviation $\bar{\sigma}$, depending on the skill, ranges from 2% to 8%. "Flat" KCs tend to have lower uncertainty, which is understandable: when the error rate for a skill is low and flat, this is easy for the model to pick up with confidence by predicting high success (high β) for that skill.

4.3 Comparison of KC models

By better estimating and controlling the uncertainty in learning curves, we can more reliably compare how skills are acquired according to different KC models.

In Figure 3 we show the same skill, *compose-by-multiplication*, as modeled by the 12-skill model *context*, and by the 15-skill model *orig*. The shapes of the learning curves are very similar, which is not surprising as both KCs are associated to the same items, and estimated from the same student outcomes. Despite differences due to the influence of other KCs in the models, the resulting values of β and γ are similar.

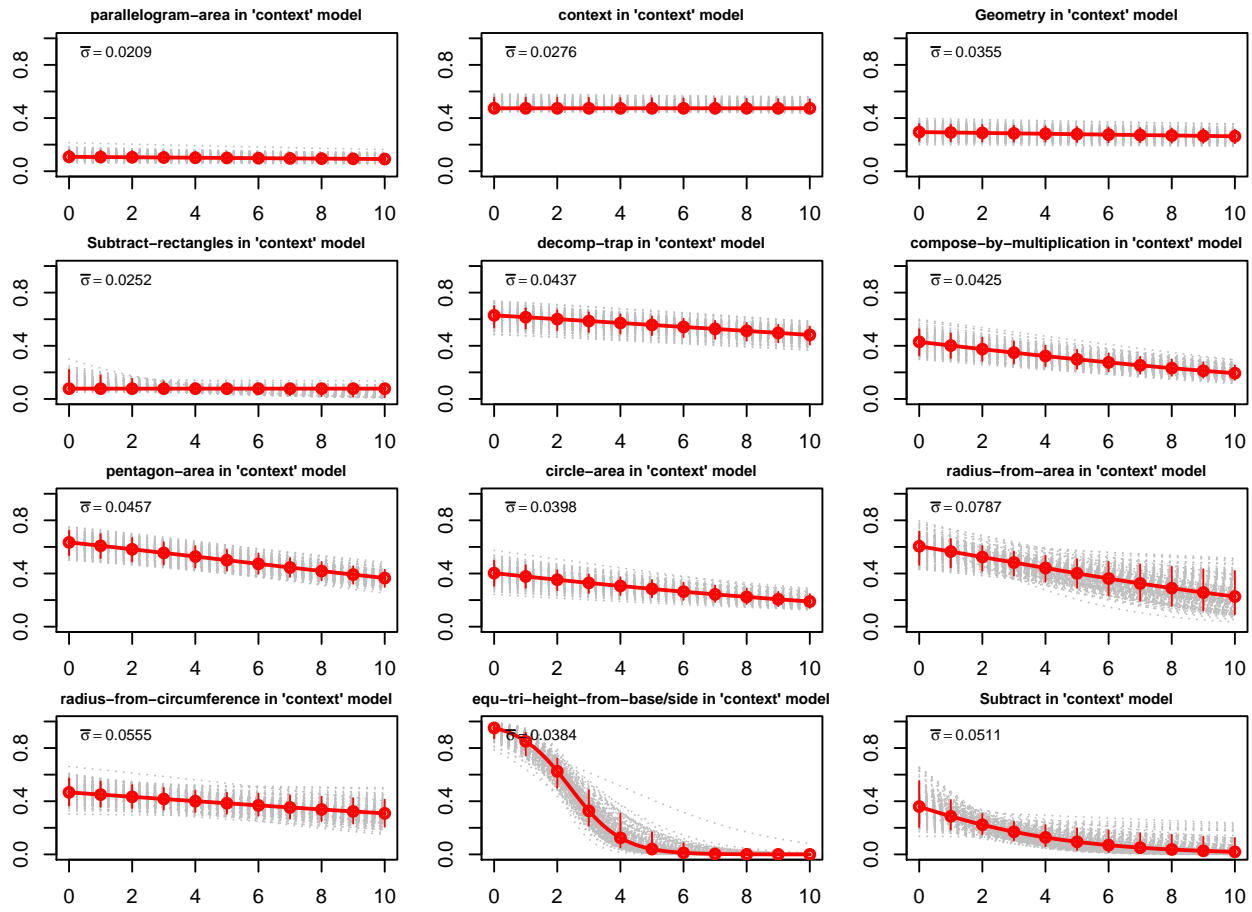

Figure 2: All learning curves with confidence intervals for KC model context.

Figure 3: KC compose-by-multiplication from KC models context (left) and orig (right). $\bar{\sigma}$ is the average uncertainty across opportunities (lower is better).

The error bars, however, show that the confidence is slightly better in the *orig* model, showing an average dispersion of around 3.5% error across the learning curve (versus 4.3% in *context*). This shows that even in a model with more KCs, learning curves can be modelled with higher confidence.

Our second example, in Figure 4, compares similar skills, *compose-subtract* from *arith*, and *Subtract* from *orig*. Again, the general shape of the learning curves are similar, due to similar values for the estimated β and γ in each model.³ The sampled learning curves also seem quite similar, sug-

³For *arith*, $\beta = .588 \pm .524$ and $\gamma = .329 \pm .200$, while for

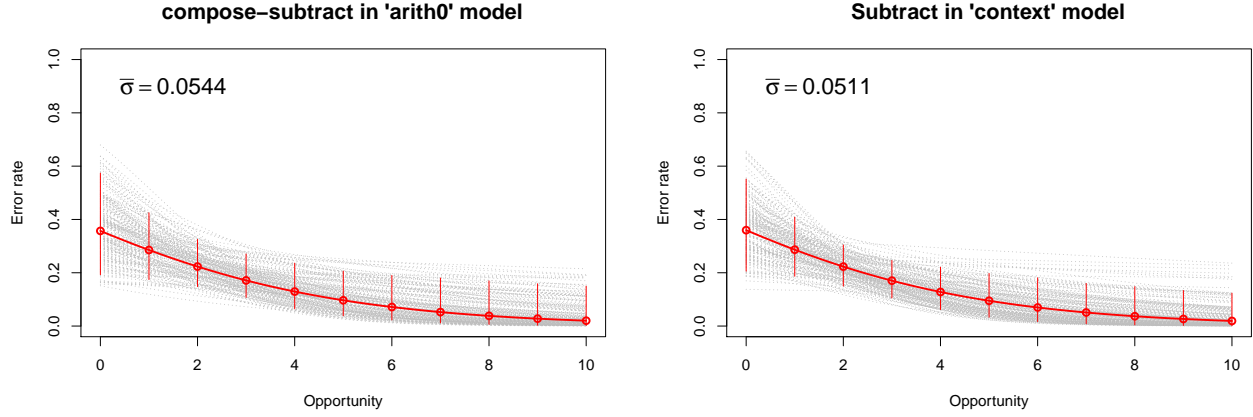

Figure 4: KC compose-subtract from model arith (left) and KC Subtract from orig (right). $\bar{\sigma}$ is the average uncertainty across opportunities (lower is better).

Figure 5: Structure of the correlation between β (y-axis) and γ (x-axis) for all KCs in model context.

esting that both KC models represent that skill with similar levels of confidence. This is confirmed by the value of the average dispersion, which is 5.4% for one model and 5.1% for the other. We see again that the different number of KCs has limited impact on how confident the models are on a particular skill.

5. DISCUSSION

Figure 1 (left) showed that there is a strong correlation between the sampled values of β_{11} and γ_{11} . The impact of this correlation on the actual learning curve is that, according to the model, this knowledge component can be modeled by a higher easiness (starting with lower error) and lower learning rate (flatter curve), or by a lower easiness and higher learning rate (i.e. starting higher but dropping faster). This finding actually generalizes to the entire KC model, as shown by the correlation matrix in Figure 5. We see that there is a consistently strong *negative correlation* between the β and γ parameters for each knowledge component, due to this compensatory mechanism. There are also some correlations between parameters of different KC, which may suggest some compensatory effects in the AFM model.

context, $\beta = .576 \pm .523$ and $\gamma = .336 \pm .200$.

One straightforward outcome of this work is that the proposed method provides a much better estimate of the confidence in a learning curve than the method proposed in [7], which relied on the marginal distribution of AFM parameters β and γ and used the boundaries of straight confidence intervals on each parameter independently. We included their 95% confidence interval as black crosses in Figure 1: that suggests that the uncertainty on the learning curve is high up to 8 or more opportunities. By contrast, our approach shows that the actual uncertainty is much better controlled, and that the skill is essentially learned by opportunity 5 or 6.

In this paper, we have worked with the basic learning curve called the *individual learning curve* in [9] or the *idealized learning curve* in [8]. We note that this work can be applied to any learning curve that relies on the parameters of the AFM model. This includes in particular the *completed learning curve* [9], where empirical observations of success/failure are completed by model estimates.

In previous work, Harpstead and Aleven [10] used empirical learning curve analysis to inform educational game design. They derive empirical curves and AFM-fitted curves, with standard errors on the curves, using a completely different approach from ours. Contrary to the approach advocated here, which relies on the core uncertainty on model parameters resulting from a maximum (penalized) likelihood estimation, their learning curves and error bars are obtained using non-parametric smoothing (LOESS [4], presumably from the `stat-smooth` function of the `ggplot2` R package). On the empirical measurements of success, this produces learning curves that are based on observations alone, and therefore may not have the desirable properties enforced by the AFM model, such as monotonicity (decreasing learning curves). On the fitted AFM predictions, those properties are enforced and apparent from the learning curves.⁴ Two key differences with our approach, however, are:

1. The use of fitted AFM values to produce error rate

⁴Blue curves in [10], Figs 3, 4 and 7.

predictions does not take into account the uncertainty in parameter values due to estimation from a finite sample, and

2. The width of the error bars are directly impacted by the number of students at each opportunity, typically resulting in widening error bars as attrition kicks in. By contrast our sampling-based algorithm often yields narrowing error bars as opportunities increase and the error rates near zero (for all sampled parameters).

A more systematic study of differences between our approach and the non-parametric smoothing of model estimates would require further study. The opportunity of combining both approaches in order to take into account the uncertainty due to parameter estimation and sampling uncertainty across the finite set of students seems particularly promising.

6. CONCLUSION

In this contribution, we provided a principled way to estimate and control the confidence in learning curves derived from the Additive Factors Model. Error bars on the learning curves account for the statistical uncertainty associated with estimating the AFM model from a finite set of students. They allow to more accurately and more confidently interpret how skills are acquired by students. We showed how this allows to characterize learning for all skills of a KC model of a geometry tutoring course. We also showed how modeling the confidence of learning curves can help compare how two different KC models represent the same skill. Our approach was illustrated here on one type of learning curve, but it can be applied to any alternative learning curve, as long as it can be computed from the usual AFM parameters. In addition, the same idea can be applied in a straightforward way to any cognitive diagnostic model for which a covariance on parameters can be computed. This includes in particular, models estimated by penalized maximum likelihood. For instance, the Individualized-slope Additive Factors Model (iAFM) [16], that extends AFM with a student learning rate, could be an excellent candidate to our method, especially as authors noticed that iAFM "[student] learning rate is significantly related to estimates of student ability". Finally, our hope is that this work will help spread the use of learning curves with well-controlled confidence among practitioners of AFM.

ABSTRACT

Over the past decade, machine learning has become an integral part of educational technologies. With more and more applications such as students' performance prediction, course recommendation, dropout prediction and knowledge tracing relying upon machine learning models, there is increasing evidence and concerns about bias and unfairness of these models. Unfair models can lead to inequitable outcomes for some groups of students and negatively impact their learning. We show by real-world examples that educational data has embedded bias that leads to biased student modeling, which urges the development of fairness formalizations and fair algorithms for educational applications. Several formalizations of fairness have been proposed that can be classified into two types: (i) group fairness and (ii) individual fairness. Group fairness guarantees that groups are treated fairly as a whole, which might not be fair to some individuals. Thus individual fairness has been proposed to make sure fairness is achieved on individual level. In this work, we focus on developing an individually fair model for identifying students at-risk of underperforming. We propose a model which is based on the idea that the prediction for a student (identifying at-risk students) should not be influenced by his/her sensitive attributes. The proposed model is shown to effectively remove bias from these predictions and hence, making them useful in aiding all students.

Keywords

Fairness, at-risk students detection, decision making, student modeling

1. INTRODUCTION

Educational data mining (EDM) approaches seek to analyze student-related data with the objective of improving learning outcomes for students. Many machine learning methods have been proposed for student modeling and forecasting. However, in the past few years, concerns have emerged about the fairness of machine learning models. An investigation by

ProPublica has found that a machine learning tool COMPAS used to predict risk of recidivism exhibits alarming bias against African-American defendants. It shows that the false positive rate of African-American defendants is twice as their white counterparts (45% vs. 23%) [1]. Buolamwini et al. [3] observed imbalanced gender and skin type distributions in facial recognition datasets. Their study shows that facial recognition algorithms are more likely to misclassify darker-skinned females with error rates up to 34.7%, while the maximum error rate for light-skinned males is 0.8%. In health care, an algorithm used to guide health decisions found that African-American patients assigned the same level of risk are sicker than white patients [24].

In the domain of EDM, unfairness has also been observed. In academic performance prediction systems, social indicators have been found to predict low-performance of male students more accurately than that of female students [29]. A study by Doroudi et al. [7] showed that although personalized models were more equitable than treating all students the same, they were still not fair when relying on inaccurate models and the inequities could cascade as the amount of content increases.

Figure 1: GPA distribution by gender.

Machine learning models learn from data. If bias is recorded in data, models trained on the biased data can also be biased [3]. Bias is also observed in educational data. Figures 1 and 2 show the average GPA of students by gender and race at George Mason University over a period of ten years. The GPA of a student is his/her accumulative GPA as of the last term before graduation. In Figure 1, average GPA of male

Qian Hu and Huzefa Rangwala "Towards Fair Educational Data Mining: A Case Study on Detecting At-risk Students" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 431 - 437

Figure 2: GPA distribution by race.

students is skewed towards lower GPAs, while average GPA of female students is skewed towards higher GPAs. The average GPA of overall female students is 3.15 which is higher than that of male students 2.86. Figure 2 shows the average GPA of African-American and non-African-American students. From the figure, we can observe that average GPA of African-American students leans towards left while that of non-African-American students leans towards right. The data shows that the average GPA of African-American students is 2.86, while it is 3.03 for non-African-American students.

Biased data can lead to biased machine learning models which can be harmful to minority groups. For example, models predicting a group of students to be at-risk or underperforming can discourage them and undermine their learning outcomes. To resolve the harmful results brought about by inequity of machine learning, there are critical needs to develop fair machine learning algorithms.

In this work, we build a fair machine learning model based on metric free individual fairness. Metric free individual fairness assumes that an individual’s qualification should not be changed if his/her sensitive attribute is changed [19]. In this paper, without loss of generality we assume there are two sensitive attributes. The proposed model is composed of two classifiers. Each classifier corresponds to a sensitive group. The classifier corresponding to the individual’s sensitive attribute predicts the individual’s probability of being positive, while the probability of the other classifier indicates the individual’s probability of being positive if his/her sensitive attribute is changed. According to the definition of metric free individual fairness, the two probability distributions should be nearly identical. The proximity of the two probability distributions is treated as fairness. The closer the two distributions, the fairer the prediction is. In addition to fairness, we also care about the accuracy of the classifier. Therefore, the overall objective we seek to optimize is the accuracy of the classifier corresponding to the individual and the proximity of the distributions of the two classifiers.

The proposed model is evaluated on datasets collected from George Mason University and the task is detecting at-risk students. The experimental results show the efficacy of the

proposed model at mitigating bias. Although, the overall data shows that female and non-African-American students have higher overall performance, we observe that the bias is different for different courses. Specifically, in some courses female students belong to disadvantaged group, while in other courses male students are in disadvantaged group. This observation is useful for future work on developing fair machine learning models in educational setting.

The rest of the paper is organized as following. Section 2 discusses related work on EDM and fairness. The following section introduce preliminary on the definition of individual fairness. In Section 4, we propose our fair model for at-risk students detection. Datasets and experimental protocol is described in Section 5. Section 6 presents experimental results and analysis. The last section concludes the paper and discusses future work.

2. RELATED WORK

In this work, we focus on mitigating bias in classification tasks. We first describe related works in EDM that rely on classification. Then we describe the formalizations of fairness. Lastly, we talk about proposed methods for fair machine learning.

2.1 Classification Problems in EDM

In educational data mining, there are many tasks that can be formulated as a classification problem and several prior works have been proposed in this area such as affect detection [30], dropout prediction [4], graduation prediction [20], at-risk student detection [17, 28], knowledge tracing [31], etc.

Affect detection is the task of classifying a student’s affective states such as boredom, confusion, delight, concentration and frustration by using sensor [26] and sensor-free [2] data. Vinayak et al. [15] proposed to predict student dropout using a Naive-Bayes classifier. Ojha et al. [25] proposed SVMs, Gaussian Processes and Deep Boltzmann Machines for student’s graduation prediction using factors such as pre-university preparation. A set of human-interpretable features have been engineered by Polyzou et al. [28] for at-risk student detection. All these tasks can be formulated as a classification problem. However, all these works did not consider the potential bias and discrimination of the models. In this work, we try to build a general method that can be used for different kinds of tasks. To test the proposed method, we focus on the task of identifying at-risk students.

2.2 Fairness Formalizations

Over the years, different formalizations of fairness have been proposed that focus on different aspects. For example, statistical parity [11] requires that the probability of being predicted as positive across all the groups should be nearly the same. Equal odds imposes the constraint that the true positive rate should be the same for all the groups [14]. Equal opportunity requires a qualified individual should be predicted as qualified regardless of his/her sensitive attribute [14]. Another type of fairness formalization focuses more on individual level. The notion of individual fairness proposed by Cynthia et al. [8] assumes that similar individuals should be treated similarly. However, the requirement of a

problem-specific similarity metric limits its adoption [5]. Hu et al. [19] proposed metric free individual fairness based on the assumption that the prediction outcome of an individual should not be influenced by the individual's sensitive attribute. The elimination of similarity metric makes implementation of metric free individual fairness easier.

2.3 Fair Machine Learning Algorithms

Several algorithms have been proposed to achieve individual fairness. Based on John Rawls' notion of fair equality of opportunity, Joseph et al. [21] proposed an individual fairness notion that a worse individual should never be favored over a better one. The unfairness comes from the prediction's dependence on sensitive attribute. To remove the dependence, Zemel et al. [32] proposed learning a fair representation which does not contain sensitive information. The representation is a cluster of embedding vectors. Following the idea of learning fair representation, Edwards [9] proposed to remove sensitive information from the learned representation by using adversarial learning. The input feature vectors are mapped to an embedding vector by an encoder. An adversary tries to predict the sensitive attribute from the representation. The encoder and the adversary plays a minimax game to remove sensitive information. The fair representation learning algorithms achieve individual fairness by first learning a representation and then training a classifier based on the learned representation. Our proposed model directly puts fairness constraints on the predictions.

3. PRELIMINARIES

In this section, we discuss the formalization of individual fairness.

3.1 Individual Fairness

Cynthia et al. [8] introduces the concept of individual fairness, which is based on the idea that similar individuals should be treated similarly. This definition requires a similarity metric measuring the similarity between two individuals. Given two individuals x_i and x_j , a classifier H is individually fair if the difference of the predictions between the individuals are upper bounded by their dissimilarity. The definition is as following

$$D(H(x_i), H(x_j)) < d(x_i, x_j) \quad (1)$$

where D is the distance measure between the outputs of the classifier and d is the distance metric between the two individuals. The drawback of this definition is that a similarity metric is required. A similarity metric guaranteeing fairness is problem specific and requires strong assumptions, which obstructs its adoption [5].

3.2 Metric Free Individual Fairness

Hu et al. [19] proposed metric free individual fairness based on the idea that the qualification of an individual should not be influenced by his/her sensitive attribute. Thus, changing an individual's sensitive attribute should not change the prediction of a classifier. The definition of metric free individual fairness is following

$$D(P(Y|x_i, S = s_i), P(Y|x_i, S \neq s_i)) < \epsilon \quad (2)$$

where s_i is the sensitive attribute of individual i , D is the distance measure of the predictions, ϵ is an arbitrarily small

Figure 3: The architecture of the proposed model. The model consists of two classifiers C_0 and C_1 corresponding to sensitive attribute 0 and 1. An input vector x_i is fed into the two classifiers and the outputs are used to compute accuracy and fairness score. Note that if the sensitive attribute s_i is 0, accuracy A_0 and fairness F are combined to compute objective O_0 and only classifier C_0 is updated; otherwise, A_1 and fairness F are combined to form objective O_1 and classifier C_1 is updated.

positive number. This definition eliminates the requirement of a similarity measure between individuals. In this work, we develop a fair model based on this definition.

4. METHODS

4.1 Problem Statement

In this work, we focus on the task of identifying at-risk students. Given a student i with $((x_i, s_i), y_i)$, $x_i \in \mathbb{R}^P$ encodes the student's grades in courses taken prior to the target course; $s_i \in \{0, 1\}$ is the student's sensitive attribute such as gender or race; $y_i \in \{0, 1\}$ is the ground truth label indicating whether a student is at-risk (1) or not (0). We focus on a binary sensitive attribute, though our method can be easily extend to scenarios where the sensitive attribute is n-ary. We want to build a classifier to predict if a student will underperform in a future target course. The classifier needs to satisfy two constraints: 1) make predictions as accurate as possible and 2) the output of the classifier is individually fair as specified by Equation 2.

The model is trained in a course-specific manner, namely, we train a model for each target course. Given a target course, we extract all the students who have taken it. The courses these students have taken prior to the target course are extracted as prior courses. The students' grades in the prior courses are extracted to form a matrix X and the students' grades in the target course are Y . Students' sensitive attributes are denoted as S . We train a course-specific model on (X, Y) to predict whether students who have not taken the target course will fail it or not. Note that sensitive attributes S are not used as features.

4.2 Proposed Algorithm

In this section, we present the proposed model, multiple cooperative classifier model (MCCM). Figure 3 shows the

architecture of the proposed model. The model is composed of two classifiers, each of which corresponds to a sensitive attribute, e.g., male or female. Given an individual $((x_i, s_i), y_i)$, the feature vector x_i is fed into the two classifiers. The output of the classifier corresponding to s_i is the individual's probability of being positive, while the output of the classifier corresponding to $1 - s_i$ is the individual's probability of being positive if his/her sensitive attribute is changed. Based on the assumption of metric free individual fairness, to be fair the difference between the outputs of the two classifiers should be ignorable. In this work, the difference is the KL-divergence of the two outputs. In addition to fairness, we also care about the accuracy of the classifier. Therefore, for student i , the objective function we seek to optimize is as following

$$L_i = -y_i \log \hat{p}_{s_i, i} - (1 - y_i) \log(1 - \hat{p}_{s_i, i}) + \lambda \text{KL}(\hat{p}_{s_i, i}, \hat{p}_{1-s_i, i}) \quad (3)$$

where λ is a hyperparameter trading off between accuracy and fairness, $\hat{p}_{s_i, i}$ is the probability of being positive predicted by classifier s_i and $\hat{p}_{1-s_i, i}$ is the probability predicted by classifier $1 - s_i$. Note that, for L_i only the classifier corresponding to s_i is updated. The classifiers are feed-forward neural networks with two hidden layers. The activation function is chosen to be ReLU [12]. Dropout [16] is used to prevent overfitting.

Algorithm 1: Multiple Cooperative Classifier Model

Input : Data $D = \{((x_i, s_i), y_i)\}_{i=1}^N$, learning rate α , λ , number of iterations T , classifier C_0 and C_1 .

```

1 Initialize parameters  $\{\theta_0^0, \theta_1^0\}$ 
2 for  $t = 1, \dots, T$  do
3   Sample example  $((x_i, s_i), y_i)$  from  $D$ 
4   Feed  $x_i$  into classifier  $C_{s_i}$  and  $C_{1-s_i}$ 
5   Compute the loss  $L_i$  according to equation 3
6    $\theta_{s_i}^{t+1} = \theta_{s_i}^t + \alpha \frac{\partial L_i}{\partial \theta_{s_i}^t}$ 
7 return  $\{\theta_0^T, \theta_1^T\}$ 

```

5. EXPERIMENTAL PROTOCOL

5.1 Datasets

To evaluate the proposed model, we collect ten-year data at George Mason University from Fall 2009 to Fall 2019. We choose top five majors including Biology (BIOL), Civil Engineering (CEIE), Computer Science (CS), Electrical Engineering (ECE) and Psychology (PSYC). We only choose a course if there are at least 300 students who have taken it. We use a student's grade in prior courses to predict whether a student is at-risk of failing a target course. While preprocessing the data, we exclude courses that are not relevant to a major such as elective courses. Table 1 shows statistics of the data. From the table, we can see clear gender difference for different majors. Female students tend to choose Biology and Psychology majors, while male students are more prone to engineering majors such as Civil Engineering, Computer Science and Electrical Engineering. Overall, the proportion of African-American students is relatively small, especially for Civil Engineering and Computer Science.

We build course specific models, namely, for a target course we train a classifier to predict whether a student will fail

that course in the future. We define as at-risk student if the student's grade is lower than 3.0. Given a target course, the data related to that course is split into 75%, 15%, 15% for training, validation and testing, respectively.

5.2 Baselines

As in this work we focus on individual fairness, we compare our proposed model with several individually fair algorithms.

5.2.1 Logistic Regression (LR)

This baseline does not have a fairness constraint. It directly predicts if a student is at-risk or not. The input is a feature vector encoding a student's grades in prior courses. The output is the student's probability of failing the target course.

5.2.2 Rawlsian Fairness (Rawlsian)

The concept of Rawlsian fairness is that a worse candidate should never be favored over a better one. Joseph et al. [21] proposed an individually fair algorithm utilizing a contextual bandits as building block to implement Rawlsian fairness.

5.2.3 Learning Fair Representation (LFR)

The unfairness of a prediction comes from the correlation of the output with the sensitive attribute. Zemel et al. [32] proposed to remove the correlation by learning an intermediate representation and train a classifier on it.

5.2.4 Adversarial Learned Fair Representation (ALFR)

Edwards et al. [9] propose to remove sensitive information from representation by adversarial learning. An encoder maps the original feature vector to a latent embedding vector, from which an adversary tries to predict the sensitive attribute. While the adversary tries to predict the sensitive attribute, the encoder seeks to generate a representation that prevent the encoder from predicting it.

5.3 Evaluation Metrics

To evaluate if the proposed algorithm satisfy the accuracy and fairness constraints, we utilize three evaluation metrics **accuracy**, **discrimination** and **consistency**.

The **accuracy** metric assesses the predictive accuracy of the model, defined as following

$$\text{acc} = \frac{\sum_{i=1}^N \mathbb{1}(y_i = \hat{y}_i)}{N} \quad (4)$$

where N is the number of examples, \hat{y}_i is the prediction and y_i is the ground truth label.

Discrimination measures the difference between the groups' rate of being predicted as positive, mathematically expressed as following

$$\text{discr} = \left| \frac{\sum_{i=1}^N \mathbb{1}(s_i = 0) * \hat{y}_i}{\sum_{i=1}^N \mathbb{1}(s_i = 0)} - \frac{\sum_{i=1}^N \mathbb{1}(s_i = 1) * \hat{y}_i}{\sum_{i=1}^N \mathbb{1}(s_i = 1)} \right| \quad (5)$$

Consistency compares the predicted results of an individual with his/her k -nearest neighbors. If the predicted results

Table 1: Dataset Statistics

Major	#S	#C	#G	#M	#F	#AA	#NAA
BIOL	6,127	16	124,716	1,927(31.45%)	4,200(68.55%)	759(12.39%)	5,368(87.61%)
CEIE	450	7	23,708	338(75.11%)	112(24.89%)	27(6.00%)	423(94.00%)
CS	2,430	11	90,819	1,942(79.92%)	488(20.08%)	157(6.46%)	2,273(93.54%)

PSYC	5,110	17	84,504	1,200(23.48%)	3,910(76.52%)	694(13.58%)	4,416(86.42%)

#S total number of students, #C number of courses for prediction, #G total number of grades
 #M number of male students, #F number of female students, #AA number of African-American students
 #NNA number of non-African-American students.

is close to the results of the neighbors, consistency is high and the algorithm is fair. Consistency is defined as following

$$\text{consist} = 1 - \sum_{i=1}^N \frac{\sum_{n=1}^K |\hat{y}_i - \sum_{j \in \text{kNN}(x_i)} \hat{y}_j|}{K} \quad (6)$$

where $\text{kNN}(x_i)$ is the k -nearest neighbors of individual i .

We use Gower similarity [13] to measure the similarity between individuals. Gower similarity is defined as

$$\text{Gower}(i, j) = \frac{\sum_{k=1}^N w_k S_{ijk}}{\sum_{k=1}^N w_k} \quad (7)$$

where N is the number of features and w_k is the weight of the k -th variable, in this paper the weights are set to one; S_{ijk} is the contribution by the k -th variable. If the k -th variable is continuous, S_{ijk} is defined as

$$S_{ijk} = 1 - \frac{|x_{ik} - x_{jk}|}{r_k} \quad (8)$$

where x_{ik} is the value of k -th feature of i and r_k is the range of values for the k -th variable. If the k -th variable is categorical, S_{ijk} is 1 if $x_{ik} = x_{jk}$ or 0, otherwise.

6. EXPERIMENTAL RESULTS

6.1 Results and Analysis

We train a classifier for each course in a major to predict if a student will fail that course. The predictions are evaluated by using accuracy, discrimination and consistency. The results are averaged across the courses in a major. Table 2 shows the experimental results with gender as sensitive attribute. From the table, we can see that the proposed model **MCCM** achieves the best performance in mitigating bias in terms of discrimination. It is able to achieve both group fairness and individual fairness, although, it is designed for achieving individual fairness. The reason is that group and individual fairness are highly correlated so that achieving one helps achieving the other.

The predictions from **LR** model is highly biased as there is no fairness constraint imposed on it, but it performs well with respect to predicting accuracy. On average, the discrimination of **LR** is 7.3%. Other methods achieve fairness at the cost of accuracy. It is interesting to see that **Rawlsian** is not able to remove bias and in some cases it leads to even more unfair predictions. **Rawlsian** is based on the idea that a worse candidate should never be favored over a better one, which is implemented by interval chaining that is a weak fairness constraint. We can also observe from the

table that different majors have different level of bias, e.g., Psychology has the least bias while Computer Science has the highest bias with respect to the predictions of **LR**. The experimental results with race as sensitive attribute is shown in Table 3. The results are similar to those with gender as sensitive attribute.

6.2 Fine-grained analysis of the bias

To have a fine-grained view of the bias, we look at the data and predictions at the course level. In this section, we analyze the bias embedded in the data and predictions from **LR** and the proposed model **MCCM**. Figure 4 shows the fine-grained results with gender as sensitive attribute. For Figure 4, the data bias is that the proportion of at-risk female students subtracts the proportion of at-risk male students. Positive bias means female students are more likely to be predicted as at-risk; otherwise male students are more likely to be predicted as at-risk. For the predictions from the models, the bias is the female students' average probability of being predicted as at-risk students subtract that of male students.

First of all, as stated in Section 1, the overall data such as overall GPA by gender shows that male is minority groups. However, when looking at the course level, different courses have different minority groups. Figure 4 shows that in some courses male students are less likely to be at-risk. This insights can be used to inform future fairness work in educational data mining that a course specific model is desirable, considering that different courses have different minority groups. From the figures, we can also observe that data and machine learning models might have different bias direction. For example, in Figure 4(a), for course C0 the data bias is against male while **LR** and **MCCM** is against female. In addition, data bias does not necessarily lead to predictive bias. For example in Figure 4, all the courses show data bias. However, a no-fairness-constraint classifier, e.g., logistic regression has fair predictions in many courses.

7. CONCLUSION AND FUTURE WORK

The concerns about bias and discrimination of machine learning models are rising with the increasing of their adoption. In educational setting, we observe bias from a real-world dataset and machine learning models without fairness constraints exhibit non-ignorable biased predictions. Machine learning models are intended to aid students with their learning. However, unfair treatment of students can undermine their learning and graduation. To mitigate discrimination in educational data mining, in this paper, we proposed a fair machine learning model satisfying metric free individual

fairness. We evaluate the model’s performance on removing unfairness on datasets collected from an anonymous University. The results show the efficacy of the model on removing bias. Compared to other domains, educational data mining has its own characteristics. For example, in our dataset, when looking at university level, male and African-American students are biased against. However, at course level, different courses have different bias direction. This insights inform that future work on fairness in educational data mining should design course-specific models. In this work, we treat gender and race separately in terms of removing bias. In the future, we want to build models that treat gender and race as sensitive attributes simultaneously.

ABSTRACT

National failure rates seen in undergraduate introductory CS courses are quite high. In this paper, we develop a predictive model for student in-class performance in an introductory CS course. The model can serve as an early warning system, flagging struggling students who might benefit from additional support. We use a variety of features from the first few weeks of the course such as scores on assignments, interaction with the online textbook, and participation with the in-class polling system in order to train our models. We compare the performance of a number of machine learning algorithms on predicting final exam scores as well as final course grade. We find that the Support Vector Machine and AdaBoost are the most effective, and that we can achieve increasingly accurate predictions as we use data from further into the course. The regression coefficients give us insights into which features are most correlated with student success, suggesting that certain types of assignments are more indicative of learning than others.

Keywords

education data mining, performance prediction, early warning system

1. INTRODUCTION

An enduring challenge in higher education is student dropout. National studies [1] have reported a relatively stable average six-year graduation of approximately 60% over the past decade. The problem is acute in STEM (Science, Technology, Engineering and Mathematics) fields where a well-trained and educated workforce is essential for national growth and economy. As the volume and variety of data collected in both traditional and online university offerings continue to expand, educational data mining [1, 20] provides the promise to assist students and improve overall student retention.

Noah Hunt-Isaak, Peter Cherniavsky, Mark Snyder and Huzefa Rangwala "Using online text books and in-class quizzes to predict in class performance" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 438 - 443

Close to 30% of the students who enrolled in CS 112, the introductory CS course at George Mason University, during the Fall 17 and Fall 18 semesters failed the course. This is close to the national average pass rate in CS1 courses found by Watson and Li [23].

The focus of this paper is to develop a model for predicting student performance in a course that they are currently enrolled in based on performance in the first few weeks of the course. An accurate predictive model may serve as an early warning system which would alert the professor to students who are struggling, at which point additional support could be provided. Attempting to make predictions too early on in the course would result in inaccurate predictions, while waiting too long will mean it is too late to take any preventative action. Howard et al. suggest that the optimal time to employ such early warning systems is right around the midway point of the course, as this provides a good balance between reasonable predictive accuracy while still allowing time to make corrective changes [6].

In this paper we extract features that capture student behaviors such as consistency, dedication, and grit, and use these alongside the gradebook to make accurate predictions as early as possible. We investigate various machine learning (ML) regression algorithms including Ridge, Lasso, Elastic-Net, Support Vector Machine, AdaBoost, Gradient Boosting, Bagging, and Random Forest. Each algorithm is tuned by applying a grid search to the parameters space. We predict both final exam scores and final course scores, comparing the different models' prediction performance on both.

Finally, we examine the coefficient weights of the most successful models to determine which features are the most significant in making predictions. Discovering patterns which seem to help or hurt students could help the professor to better structure the course in the future, as well as discover more general trends which could be applied elsewhere.

2. PRIOR WORK

A number of attempts have been made at developing grade prediction models and early warning systems similar to what we wish to accomplish here. Most commonly, this has been done in the context of massive open online courses (MOOCs) such as in Ren et al. [19]. Li et al. [16] made an early

prediction model for a blended course. They had access to homework and test scores from the first 6 weeks of the course and used this data to predict students' final letter grades. However, they were only able to slightly improve upon a base model of predicting all A's (47.8% accuracy) by using an SVM (51.4% accuracy). This was probably a result of the course being too easy, which resulted in a fairly uniform data set. Elbadrawy et al. [11] looked at predicting performance on activities within a course, also using multi-regression models. They took into account a combination of features including demographic information, historical performance and course interaction data from the LMS. Another study done by Nam and Samson [17] investigated the impact of student behavioral signals in early warning system predictions. Costa et al. [4] investigated the effectiveness of four algorithms in predicting student failure in two computer science courses along with the effect of preprocessing data and fine tuning the algorithms on their performance. The preprocessing and fine tuning was found to improve performance for the most part. Ren et al. [18] developed Additive Latent Effect Models to predict student performance in a future course. It used factors from the student, course, and instructor for the prediction. The model performed better than all the baselines. Crossley et al.[5] did a study that used click-stream, language, and demographic data to predict the performance of elementary school students in a math course. The click-stream and language data was from an online math tutoring system. They found that the linguistic, click-stream, and demographic factors explained 14% of the variance in the math score and random factors of the student explained 30% of the variance in the math score. Elbadrawy et al. [10] developed a personalized linear multiple regression (PLMR) and other models to predict grades in a future course and grades in a future assignment within regular courses and a massive open online course (MOOC). Matrix factorization (MF) and PLMR outperformed traditional models in predicting student success in a future course and PLMR was useful in predicting grades within regular courses and a MOOC.

Several papers have covered the usage of zyBooks in CS courses, the online interactive textbook used in the course here. Most students complete the textbook [8, 7, 9]. The relationship between completion rate of the textbook and percentage of the grade that the textbook work is worth levels off at a certain point [8, 9]. The acquisition rate of zyBooks is higher than traditional textbooks [7]. Students mostly do not cheat when using zyBooks [8, 9]. Students' use of zyBooks is stable throughout the semester [7].

Unlike most of the prior studies which have been done in this area, we are exclusively using data from within the context of the course itself (i.e. we don't consider any student demographic or background information). We do, however, use a wider range of interaction data for students.

3. DATASET

Our data is taken from two sections of George Mason's introductory CS course, CS112. CS112 is taught in Python and covers a range of basic programming concepts including variables, conditionals, functions, loops, dictionaries, files, classes, and recursion. The courses were taught during the Fall semesters of 2017 and 2018, for an overall enrollment of 1,197 students. It includes each student's grade book from the semester, including scores on homework, labs, projects, and tests. The grade book also contains additional information such as whether or not the student was flagged for an honor code violation and how many of their allotted late submissions were used. CS112 was taught with an accompanying interactive online textbook, zyBooks, from which we have submission logs. Additionally an online polling system, Pytania [21], was used routinely during lectures. The final grade composition for the course was computed as follows:

Category	Percent	Notes
Projects	40%	drop 1 lowest
Labs	10%	drop 2 lowest
Pytania Particip.	2%	up to 1% bonus for correct answers
zyBook readings	3%	(drop 3 lowest-completion sub-sections)
Tests	20%	(10% each test)
Final Exam	25%	(must pass final to pass class)

Note that students were required to pass the final in order to pass the course, so that even if a student's raw score would have given them a D or above, they ended up with an F if they failed the final (this impacted 82 out of the 1,197 students, or about 6.85%). The overall grade distribution across both semesters of the course can be seen in Figure 1, which uses the following letter grade assignment to map raw scores to letter grades.

Grade	Score	Grade	Score	Grade	Score	Grade	Score
A+	98%	B+	88%	C+	78%	D	60%
A	92%	B	82%	C	72%	F	0%
A-	90%	B-	80%	C-	70%		

4. METHODS

All of the students who were flagged with an honor code violation were removed from the data set and not considered when making predictions. We consider their data as inaccurate records of effort, ability, and expected outcomes.

4.1 Feature Engineering

New features were engineered based on the Pytania and zyBook data in an attempt to capture behavioral patterns of students. In particular, we aimed to represent qualities such as participation, consistency, and grit, all of which may be important factors in predicting success. Note that the Pytania data is essentially a measure of attendance and in-class participation.

The Pytania data in its raw form consisted of rows corresponding to a single question answered by a single user with a timestamp and whether or not the question was answered correctly. We needed to extract from this a set of features for

each user which could be fed into our predictive model. The first attempt was to simply add two new features for each student, the number of Pytania questions attempted and the number answered correctly. However we could capture more information from the data by also taking into account the chronology of when students were answering questions. For example, a student who missed the first week but has answered every question afterwards ought to be more highly considered than one who answered everything for the first couple of weeks but has since dropped off. To capture this information, binning was used to create multiple new features dependent on the number of questions answered within a certain time frame. In particular, a feature is added for the number of question answered in each 1 week period through the semester. For example, there is a bin for the most recent week, and another for the week before that, and so on until the start of the semester. In this way we expect the model to weight more recent bins more highly as they are more likely to predict future performance compared to using past performance as a predictor.

We also wanted to have some measure of consistency of student participation. This was measured by taking the standard deviation of the weekly bins. The result was added as a new feature to the model. Students with a high amount of inconsistency would perhaps be expected to perform worse, or at least be more difficult to predict accurately.

The zyBook data was similar in form to the Pytania data, recording individual attempts at a question by a student. Unlike with the Pytania data, students could have multiple attempts at each question. Across all users, the average number of submissions per question is 1.5. The features extracted from this data include total number of attempts (submissions), total number of correct submissions (max one per problem), and average earliness (measured as the difference in time between the problem due date and the first correct submission). The correct submissions feature is divided up by chapters from the textbook, and special ‘challenge’ problems, which are more difficult and involved, are handled separately from regular ‘participation’ problems.

4.2 Normalization

Normalization was applied to ensure that no one feature had too dominant of an impact. Each column of features was mapped to the range 0-1 such that the max observed value became a 1 and the min value became a 0. This had a minimal positive effect on results.

4.3 Algorithms

After the features were generated, we ran experiments to determine which algorithm does the best job at predicting student performance. We tested a wide variety of regression algorithms in our experiments including Linear, ElasticNet, Lasso, and Ridge regression models [24, 22, 15, 3]. We also used the support vector regression algorithm (SVR). Finally, we used a number of ensemble algorithms including AdaBoost, Bagging, Gradient Boost and a Random Forest approach [12, 2, 13, 14]. We employed the Python module `sk.learn` for implementations of each algorithm and each algorithm was additionally tuned for optimal parameters using GridSearch (the final parameters can be seen in appendix A).

4.4 Metrics

Two relevant outcomes for prediction were examined: predicting the final RAW score in the course and predicting the score on the final exam (test 3, “T3”). Final RAW score is arguably more important to predict as this is what impacts the student’s GPA and is the most commonly used metric for success in a course. However, many of the features being used to predict RAW score are also directly correlated with RAW scores (e.g. projects make up 40% of the final course grade). This makes the prediction less meaningful as the regression weights may come to simply recreate the exact course weighting for assignment. Hence we also predict scores for the final exam, a distinct assessment which is not directly calculated from any of the other features. The final exam is also arguably a better metric for how much of the content a student was able to truly learn.

For regression tasks such as predicting the RAW score we used mean absolute error (MAE), root mean squared error (RMSE), and the coefficient of determination (R2) score as our metrics of evaluation (as defined in figure 2). Note that MAE and RMSE are in the range $[0, \infty)$, and lower scores are better. The RMSE is a commonly used metric for evaluation of regression models, which punishes big errors due to the squared error term. The MAE on the other hand weights all individual differences equally on a linear scale. The result is a more interpretable score, which represents the average error in our predictions. (e.g. a MAE of 10 while predicting final exam scores would mean that the mean prediction was 10 points off from guessing the true value). R2 is in the range $(-\infty, 1]$, where higher scores are better. The R2 score compares the effectiveness of a model to a simple baseline which predicts the mean value for each instance. A score of 0 implies a model which makes no improvement upon this baseline, while a negative score implies a model which is worse than the baseline. A score of 1 perfectly predicts each true value.

5. EXPERIMENTAL RESULTS

Figure 3 shows the resulting MAE, RMSE, and R2 scores for predicting final exam and raw scores using the first 9 weeks of data in a 16 week course. We see that the AdaBoost regressor achieved the lowest MAE score when predicting final exam scores, with an average error of 8.02. The SVR and Bagging regressors also performed well here. For predicting the raw course score, the Ridge regressor performed the best overall, with the top RMSE of 7.03, and an R2 score of 0.84. The Lasso regressor outperformed Ridge slightly in terms of MAE where it achieved a score of 5.42. For the sake of comparison, we also present a ‘baseline’ score which was calculated simply by predicting the mean value for each student (note that this baseline will have an R2 score of 0 by definition).

Using the optimal algorithms for each category from above, we ran experiments to determine how accurately we can make predictions at various points throughout the semester. In particular, we used the AdaBoost regressor for predicting final exam score and the Ridge regressor for predicting final RAW score. Figure 4 shows the results for this experiment, plotting MAE scores as a function of the number of weeks of data used. As expected, the accuracy of the prediction improves as more data is available for use through the first

Figure 1: CS112 Grade Distribution

MAE	$\frac{1}{n} \sum y_{true} - y_{pred} $
RMSE	$\sqrt{\frac{1}{n} \sum y_{true} - y_{pred} ^2}$

Figure 3: Regression Algorithm Comparison

10 weeks of the semester. We also see that predictions of raw score are consistently better than predictions of final exam score. This makes sense as the raw score is in fact calculated directly from some of the features we are using in our predictive model, while the final exam score is not.

Figure 4: Predicting T3 score over time

Figures 6 and 7 show the values of the coefficient weights for each feature from the optimal final exam and raw score models run using 8 weeks of data (see figure 5 for coefficient definitions). For final exam prediction, it is not surprising to see that performance on the first exam, T1, is the best predictor. Next, other substantial graded assignments such as projects 2 and 3 and lab 5 also have fairly high weights. The Pytania features overall have small weights, suggesting that participation in the polling system is not strongly correlated with success. It may be the case that students did not take Pytania participation very seriously as it only accounted for 2% of their semester grade. However, we do observe that pwa:0 and pwa:1, which correspond to questions answered in the most recent weekly periods, are more significant than the earlier weeks, meaning that recent activity is a better indication of a student doing well than activity early on in the course. For the zyBook features we see that each chapter has a small positive weight. The strongest positive zyBook weights are cha_lacp (the number of challenge problems successfully completed) and zy_early (the average earliness of submissions). Interestingly, zy_attempt (corresponding to the total number of attempted submissions) and extra_sub

Feature Name	Meaning
L1E	Lab 1 Exercise
L4T	Lab 4 Test
L6Q	Lab 6 Quiz
P1	Project 1
T1	Test 1
cha_lacp	Challenge zyBook problems successfully submitted
extra_sub	Resubmissions to a previously correctly submitted problem
pytania_std	Standard deviation across Pytania bins
pwa:1	Pytania participation last week
pwa:2	Pytania participation two weeks ago
zychp1	zyBook correct submissions from chapter 1
zy_attempt	Total count of zyBook submissions
zy_early	Average earliness of zyBook submissions

Figure 5: Regression Coefficients

Figure 6: Regression coefficients T3

Figure 7: Regression coefficients Raw

(corresponding to the total number of additional submissions to a problem which had already been completed) both have negative weightings. The first could be explained by the fact that students who struggle and require multiple submissions to a problem are likely weaker students. The second is more difficult to account for, as one might expect subsequent attempts at a problem for which the student already has credit to be a sign of determination to learn the material.

6. DISCUSSION

In this paper we formulated an in-class predictive model for student performance in a CS1 course taught at George Mason University. Our model used a feature set solely derived from in-class activities and assignments rather than relying on past information or demographics. We employed a variety of machine learning algorithms and tested their accuracy as a function of the number of weeks of data used from the semester. Our results show that both final raw scores and final exam scores can be predicted with a high level of accuracy as early as 6 or 7 weeks into the course. Thus it could be effectively employed as an early warning system, such that students could have a good sense of what grade they

will end up with if they remain on their current trajectory.

We note that often in cases where multiple features had equivalent direct grade contributions (due to course weighting) there was a discrepancy in the predictive power amongst these features. For example, we found that recent participation was a more relevant predictor of ultimate success than past participation, even though it is equivalent in terms of direct impact on a student's grade. Similarly, we found that engagement with certain textbook chapters, and success on certain labs and quizzes are more indicative of success than others. Thus there could be a situation in which two students have the same class grade, and yet one is flagged as a struggling student while the other is not. Herein lies the value of using such a model; it can discover nuances and patterns in student performance which an instructor (particularly in an introductory course with many students) would otherwise be unable to detect.

6.1 Future Work

In this work we considered only in-class information. It would be interesting to see how much improvement could be made to the model by also considering past information such as prior course scores and demographics. It would also be worth trying to make predictions of other CS courses, or non-CS courses, and comparing the accuracy of predictions as well as which features stand out as strong predictors.

We propose that our predictive model could serve as an early warning system, triggering intervention. However, we do not suggest exactly how or when this intervention should take place. Studies would have to be performed on different forms of intervention to determine which methods work best.

7. ACKNOWLEDGEMENTS

This material is based upon work supported by the National Science Foundation REU grant for Education Data Mining at George Mason University, award 1757064. We would also like to thank Dr. Rangwala (PI of the REU site) for his contributions to our work and his invaluable guidance throughout the research process, as well our fellow REU student participants for their continual support and encouragement.

A. GRIDSEARCH PARAMETERS

Grid search found the optimal combination of parameters for each machine learning algorithm. The following parameters were used (any unlisted used the default value from sklearn):

Ridge: alpha=1.0, solver=‘lsqr’

Lasso: alpha=0.1

ElasticNet: alpha=0.1, l1_ratio=0.9

SVR: C=1, gamma=0.001, kernel=‘linear’

AdaBoost: learning_rate=0.2, loss=‘exponential’, n_estimators=80

GradientBoost: criterion=‘mae’, learning_rate=0.01, loss=‘huber’, max_depth=None, min_samples_leaf=1, min_samples_split=10, n_estimators=80, subsample=0.8

Bagging: bootstrap_features=True, max_features=20, n_estimators=80

RandomForest: criterion=‘mae’, min_samples_leaf=0.1, min_samples_split=0.1, n_estimators=40

Online Academic Course Performance Prediction using Relational Graph Convolutional Neural Network

ABSTRACT

Online learning has attracted a large number of participants and is increasingly becoming very popular. However, the completion rates for online learning are notoriously low. Further, unlike traditional education systems, teachers, if any, are unable to comprehensively evaluate the learning gain of each student through the online learning platform. Hence, we need to have an effective framework for evaluating students' performance in online education systems and to predict their expected outcomes and associated early failures. To this end, we introduce Deep Online Performance Evaluation (DOPE), which first models the student course relations in an online system as a knowledge graph, then utilizes an advanced graph neural network to extract course and student embeddings, harnesses a recurrent neural network to encode the system's temporal student behavioral data, and ultimately predicts a student's performance in a given course. Comprehensive experiments on six online courses verify the effectiveness of DOPE across multiple settings against representative baseline methods. Furthermore, we perform ablation feature analysis on the student behavioral features to better understand the inner workings of DOPE. The code and data are available from <https://github.com/hamidkarimi/dope>.

1. INTRODUCTION

Online learning has higher dropout and failure rates than traditional education systems. For instance, the completion rates of Massive Open Online Courses (MOOCs), an extension of online learning technologies, are low (0.7%-52.1%, with a median value of 12.6%, reported by [20]). We also see similar situations in other online courses from universities such as Open University in the UK and China [19].

Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 444 - 450

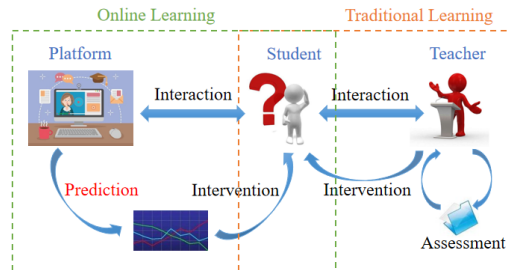

Figure 1: Visual comparison of the learning/intervention process between online and in-person education systems.

Furthermore, since students typically drop out early in the courses [33], the platform is desired to detect which student is likely to drop out (or fail) as early as possible to intervene and to hopefully prevent these negative outcomes. Then the question is how we can assess students' performance and detect those who are likely to drop out or fail in an online course. To answer this question, we first need to take a closer look at the online learning system and see how it differs from traditional learning.

As illustrated in Figure 1 (right side), in the traditional learning setting, instructors can interact with students, assess their performance, and take action to provide intervention if they sense a student is likely to perform poorly in the class. In online learning systems, however, the students primarily interact with the online platform, so we face a setting depicted in the left side of Figure 1. In this setting, there is inherently less interaction between students and instructors. More specifically, due to the high student-teacher ratio, teachers, if any, in the online learning systems are unable to comprehensively evaluate the learning gain of each student. Thus, we seek to develop a methodology that can harness the interactions of students with an online platform and accurately predict the course outcome (e.g., *pass or fail*). Such a system could then be used in real-time throughout the course to identify the students who are predicted to perform poorly and provide some intervention to them with the limited resources that are inherent in online systems.

Given the above discussion, we propose a framework named Deep Online Performance Evaluation (DOPE) to predict students' course performance in online learning. DOPE first models the student course relations of the online system as a knowledge graph. To incorporate an aggregated overview of

the students and courses in the online system, DOPE learns student and course embeddings from our knowledge graph. More specifically, we employ a relational graph neural network [34] that can handle the rich attribute information found in our knowledge graph (e.g., student demographic data). Then, our proposed approach utilizes a recurrent neural network (RNN) to encode the temporal student behavioral data into some features. More specifically, the student behavioral data is coming from student click patterns extracted and aggregated into weekly snapshots that represent how they have interacted with the online learning system. Finally, the student and course embeddings (extracted from the knowledge graph) are combined with the encoded behavioral data extracted for the given student and course and are fed to a classifier to predict a student's performance. In summary, our contributions are as follows.

1. We propose the use of a knowledge graph to model complex online learning environments to allow more rich data to be extracted as compared to representing the data in a traditional unstructured way; and
2. Our proposed framework to predict student course outcomes contains two novel components, namely a relational graph neural network to extract student and course embeddings from the formed knowledge graph and a recurrent neural network model for encoding student behavioral data according to their clicks in the online system.

2. PROBLEM STATEMENT

Suppose from the set of courses in an online system we have a subset of m courses denoted as $\mathcal{C} = \{c_1, c_2, \dots, c_m\}$. Furthermore, let there be n students having enrolled in at least one of the m courses in \mathcal{C} , which we denote as $\mathcal{S} = \{s_1, s_2, \dots, s_n\}$. For each course c_j , we assume there are some course features that can be represented as the vector $\mathbf{f}_j \in \mathbb{R}^{d_c}$ with d_c being the dimension size after encoding the course features. Similarly for each of the students s_i we assume there has been some collected demographic information that can be represented as the vector $\mathbf{d}_i \in \mathbb{R}^{d_s}$ with d_s being the dimension size after having encoded the student demographic data. In addition to the demographic data, the system is assumed to have collected some sequential behavioral data for each student s_i enrolled in course c_j that we represent as $\mathbf{B}_{ij} = [\mathbf{B}_{ij}^1, \mathbf{B}_{ij}^2, \dots, \mathbf{B}_{ij}^k]$ where $\mathbf{B}_{ij}^w \in \mathbb{R}^q$ represents an encoding of the behavior for student s_i during the w^{th} week of course c_j , k represents the number of weeks for which behavioral data was collected, and q is the dimension of the encoded weekly student behavior. In other words, we have a tensor of student behavioral data $\mathbf{B} \in \mathbb{R}^{n \times m \times k \times q}$. For each student s_i , we represent their performance outcome in course c_j as o_{ij} , where we assume there can be P outcomes (denoted by the set $\mathcal{P} \in \mathcal{P}$).

Now, given the notations listed above, we seek to learn a model $f(\cdot|\theta)$ having parameters θ such that it can predict the course student outcomes \mathcal{O} as follows:

$$M(\mathcal{C}, \mathcal{S}, \mathcal{F}, \mathcal{D}, \mathbf{B}, \mathcal{O}, f(\cdot|\theta)) \rightarrow \hat{\theta}$$

where we use M to denote the machine learning (artificial intelligence) process, \mathbf{B} is used to represent the behavioral (e.g., click) data for a given set of courses \mathcal{C} using only the first k weeks of data, \mathcal{F} represents the set of course features of \mathcal{C} , \mathcal{D} denotes the set of demographic data for the students

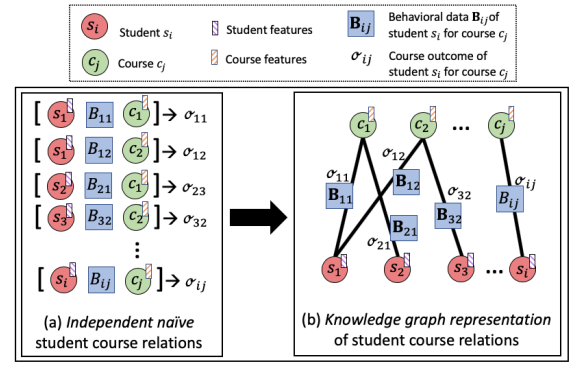

Figure 2: Visualizing the traditional representation used in prior supervised learning prediction models as compared to our knowledge graph representation.

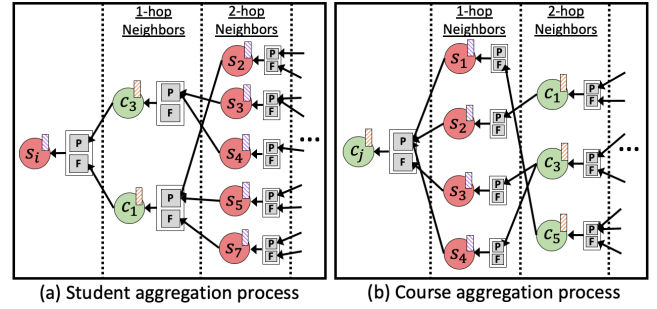

Figure 3: Visualizing the aggregation process in how both a student and course embedding are formed from their knowledge graph multi-hop neighborhood.

in \mathcal{S} , \mathcal{O} represents the performance outcomes of the students in \mathcal{S} and the learned parameters of $f(\cdot|\theta)$ are given by $\hat{\theta}$.

3. PROPOSED MODEL

In this section, we explain our proposed model in detail.

3.1 Knowledge Graph Representation

We first model the historical online course data in the form of a knowledge graph, as shown in Figure 2. Our knowledge graph formulation in Figure 2(b) offers a richer representation than a traditional independent naive student course relation representation shown in Figure 2(a). This is because through this graph structure we can leverage the relations between students and courses beyond that seen in Figure 2(a). We let $\mathcal{G} = \{\mathcal{C}, \mathcal{S}, \mathbf{X}_c, \mathbf{X}_s, \mathbf{B}, \mathbf{A}\}$ represent a knowledge graph \mathcal{G} containing the set of m course nodes \mathcal{C} , set of n student nodes \mathcal{S} , course features $\mathbf{X}_c \in \mathbb{R}^{n \times d_c}$ constructed from \mathcal{F} , student demographic features $\mathbf{X}_s \in \mathbb{R}^{m \times d_s}$ constructed from \mathcal{D} , the behavioral data \mathbf{B} representing complex sequential edge features, and an adjacency tensor $\mathbf{A} \in \mathbb{R}^{n \times m \times P}$ constructed from the P different student-course outcome relations where $\mathbf{A}_{ij}^p = 1$ if $o_{ij} \in \mathcal{O}$ and $o_{ij} = p$ (with $\mathbf{A}_{ij}^p = 0$ otherwise). Now, given the knowledge graph G , we seek to extract student and course embeddings by using a relational graph neural network.

3.2 Relational Graph Neural Network

Recently, graph neural networks (GNNs) [38, 39] have become increasingly popular due to their ability to utilize deep

learning on graph structure data. One popular class of GNNs is the graph convolutional networks (GCNs) [5, 27, 8, 7], which are constructed with roots from the classical CNNs. The general idea of these GCN models is that we would like to learn a better set of latent features. In the context of our problem, to better understand and represent a student, rather than directly using their features alone, we could use a 1-layer GCN that would incorporate the features of all the courses that the student has taken. For example, in Figure 3(a), the 1-hop neighbors would be utilized in a 1-layer GCN model taking into consideration the course c_3 that they passed and c_1 that they failed. Then, it is natural to see in Figure 3(a) that using a 2-layer GCN would further incorporate the 2-hop neighbors which would include information from all the classmates of s_i for each of the two courses they have taken, and thus providing further context into learning a more comprehensive embedding for student s_i . We specifically harness the ability of a relational graph convolutional network [34]. Next we will provide the details on how the first layer (or equivalently a 1-layer) GCN is able to construct learned representations $\mathbf{h}_{s_i}^1$ and $\mathbf{h}_{c_j}^1$ for the student s_i and course c_j , respectively, from the initial student features \mathbf{X}_s , course features \mathbf{X}_c , and adjacency tensor \mathbf{A} in our knowledge graph representation.

–**First Layer Embeddings.** First, we recall that connections between students and courses are stored in the tensor \mathbf{A} where $\mathbf{A}_{ij}^p = 1$ if $o_{ij} \in \mathcal{O}$ and $o_{ij} = p$ (with $\mathbf{A}_{ij}^p = 0$ otherwise). Thus, we define for a student s_i their set of courses for which they had outcome p as $\mathcal{N}_s^p(s_i)$. Similarly, we define for a course c_j their set of students that received the outcome p as $\mathcal{N}_c^p(c_j)$. Now, given these new notations, we can define the first layer representations $\mathbf{h}_{s_i}^1$ and $\mathbf{h}_{c_j}^1$ for the student s_i and course c_j , respectively, as follows:

$$\mathbf{h}_{s_i}^1 = \sigma \left(\mathbf{W}_{self}^1 \mathbf{X}_{s[i]} + \sum_{p \in \mathcal{P}} \frac{1}{|\mathcal{N}_s^p(s_i)|} \sum_{c_j \in \mathcal{N}_s^p(s_i)} \mathbf{W}_p^1 \mathbf{X}_{c[j]} \right) \quad (1)$$

$$\mathbf{h}_{c_j}^1 = \sigma \left(\mathbf{W}_{self}^1 \mathbf{X}_{c[j]} + \sum_{p \in \mathcal{P}} \frac{1}{|\mathcal{N}_c^p(c_j)|} \sum_{s_i \in \mathcal{N}_c^p(c_j)} \mathbf{W}_p^1 \mathbf{X}_{s[i]} \right) \quad (2)$$

where σ is an element-wise non-linear activation function (e.g., $\text{ReLU}(\cdot) = \max(0, \cdot)$ [13]), $\mathbf{X}_{s[i]}$ denotes the student features for s_i , $\mathbf{X}_{c[j]}$ denotes the course features for c_j , \mathbf{W}_{self}^1 is used to transform the self features from the original features, and \mathbf{W}_p^1 is used for transforming the features that are linked through the relation (i.e., course outcome type) p for the first layer.

–**Final Student Embeddings.** If we assume having L layers in our GCN model, we can then first define the last layer where we will obtain the student embedding $\mathbf{z}_i^s = \mathbf{h}_{s_i}^L$ for s_i as follows:

$$\mathbf{z}_i^s = \sigma \left(\mathbf{W}_{self}^L \mathbf{h}_{s_i}^{L-1} + \sum_{p \in \mathcal{P}} \frac{1}{|\mathcal{N}_s^p(s_i)|} \sum_{c_j \in \mathcal{N}_s^p(s_i)} \mathbf{W}_p^L \mathbf{h}_{c_j}^{L-1} \right)$$

where $\mathbf{h}_{s_i}^l$ represents the representation of student s_i at layer l of the GCN. Note that if we were to use a 2-layer GCN (i.e., $L = 2$) then $\mathbf{h}_{s_i}^{L-1} = \mathbf{h}_{s_i}^1$ would be coming from Eq. (1) and similarly $\mathbf{h}_{c_j}^{L-1} = \mathbf{h}_{c_j}^1$ from Eq. (2).

–**Final Course Embeddings.** If we assume having L layers in our GCN model, we can then first define the last layer where we will obtain the course embedding $\mathbf{z}_j^c = \mathbf{h}_{c_j}^L$ for c_j as follows:

$$\mathbf{z}_j^c = \sigma \left(\mathbf{W}_{self}^L \mathbf{h}_{c_j}^{L-1} + \sum_{p \in \mathcal{P}} \frac{1}{|\mathcal{N}_c^p(c_j)|} \sum_{s_i \in \mathcal{N}_c^p(c_j)} \mathbf{W}_p^L \mathbf{h}_{s_i}^{L-1} \right)$$

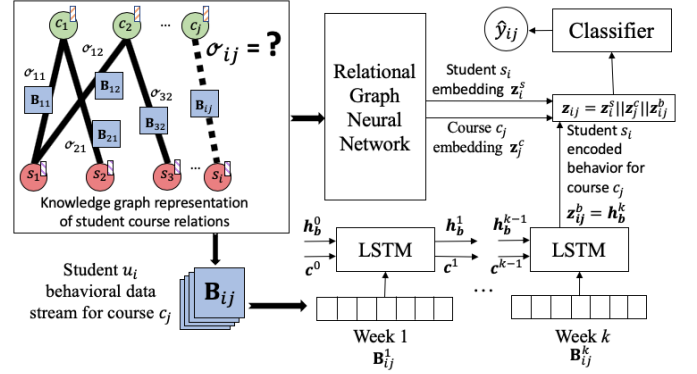

Figure 4: Visualizing the entire DOPE model consisting of both the relational graph neural network and recurrent neural network components.

where $\mathbf{h}_{c_j}^l$ is the embedding of student c_j at layer l of the GCN. Next, we will discuss how DOPE uses an RNN to encode a student's sequential behavior data associated with a given course.

3.3 Encoding Student Behavioral Data

In this part, we discuss how to encode the sequential edge features i.e., behavioural student data. To recall, when a student s_i is currently enrolled in a course c_j , by the k^{th} week we will have the features $\mathbf{B}_{ij} = [\mathbf{B}_{ij}^1, \mathbf{B}_{ij}^2, \dots, \mathbf{B}_{ij}^k]$. To better represent the behavioral data, we utilize a Long-Short Term Memory (LSTM) [16], which is an effective RNN variant that has been designed to extract temporal features from sequential data e.g., videos [25], speech [14, 25], and text [24, 23]. Furthermore, it has shown great abilities to capture temporal online user behaviors [26]. We fix the length of the behavior feature sequence for all students to be k (e.g., 10 weeks). Then for a given behavioral sequential data \mathbf{B}_{ij} , at each week $t \in [1, k]$, an LSTM unit takes the t -th week's click feature vector \mathbf{B}_{ij}^t as the input and uses LSTM formulation [16] to produce the output behavioral vector \mathbf{h}_b^t . The final output of the LSTM is $\mathbf{h}_b^k \in \mathbb{R}^b$ (i.e., output of last LSTM unit) when given the sequence \mathbf{B}_{ij} as input. Then, we set the encoded behavior of student s_i for course c_j as the e^b dimensional vector $\mathbf{z}_{ij}^b = \mathbf{h}_b^k$.

3.4 Final Course Performance Classifier

Here we combine student and course embeddings from the relational graph convolutional as well as encoded behavioral data and feed into a classifier. This can be seen in Figure 4. Given the student embedding \mathbf{z}_i^s for student s_i , course embedding \mathbf{z}_j^c for course c_j , encoded student behavior of s_i in the course c_j as \mathbf{z}_{ij}^b we form the final feature representation as follows:

$$\mathbf{z}_{ij} = \mathbf{z}_i^s || \mathbf{z}_j^c || \mathbf{z}_{ij}^b$$

where $||$ denotes concatenation and we concatenate the three components together into a single $(e^s + e^c + e^b)$ dimensional representation. For training DOPE, we use supervised learning such that labels are the outcome performances from the historical data $o_{ij} \in \mathcal{O}$ and matched with the training student and course pair (s_i, c_j) . More specifically, we construct a minibatch set \mathcal{M} that contains triplets of the form (s_i, c_j, T) where $T = o_{ij}$ (i.e., the course outcome type) and we assume the outcome type set \mathcal{T} where $|\mathcal{T}| = p$ since there are p course outcome types. The objective is then formalized in the following:

$$\mathcal{L} = \frac{1}{|\mathcal{M}|} \sum_{(s_i, c_j, T=o_{ij}) \in \mathcal{M}} \log \frac{\exp(\theta_T^{MLG} \mathbf{z}_{ij})}{\sum_{T' \in \mathcal{T}} \exp(\theta_{T'}^{MLG} \mathbf{z}_{ij})} + \lambda \text{Reg}(\theta^{RGCN}, \theta^{LSTM}, \theta^{MLG}) \quad (3)$$

where the classifier first maps \mathbf{z}_{ij} to a p dimensional vector through the parameters θ^{MLG} (since we have p different outcomes, i.e.,

Table 1: The description of the dataset.

Name	Train Periods	Test Periods	#Students
SS_1	2013J	2014J	735
SS_2	2013B, 2013J	2014B, 2014J	6622
SS_3	2013J, 2014B	2014J	2366
ST_1	2013B, 2013J	2014B, 2014J	5745

ST_3	2013B, 2013J	2014B, 2014J	7092

link labels in the knowledge graph) and then utilizes the softmax function to get the outcome probabilities.

4. EXPERIMENTS

In this section, we conduct some experiments to verify the working of our proposed method.

4.1 Dataset and Experimental Settings

Online education platforms utilize virtual learning environments (VLEs) to collect records about all students' interactions and provide the opportunity for analyzing students' learning behavior. In this study, we use the data of The Open University Learning Analytics Dataset (OULAD) [29], which contains 22 open university courses for years 2013 and 2014 and 32,593 students. The dataset includes student demographic information, student assessment results, and daily interactions with the university's VLEs (10,655,280 entries). For each year, courses are offered in two distinct modules denoted as B and J (essentially they are similar to 'semester' in the conventional education system) where each module takes around 35 to 40 weeks long. The outcome of a course for a student can have four different categories including *Distinction*, *Pass*, *Fail*, and *Withdrawn*. We use OULAD and select three social science courses (i.e., SS_1 , SS_2 , and SS_3) and three Science, Technology, Engineering, and Mathematics (STEM) courses (i.e., ST_1 , ST_2 , and ST_3) as demonstrated in Table 1.

To represent the behavioral data, we count the different number of weekly clicks a student makes e.g., accessing resources, webpage click, forum click, quiz attempt, and so on. The size of each weekly behavioral vector is 20. Further, course attributes include two one-hot encoding vectors, one for representing a course among 6 courses, and the other one for holding either the course is social science or STEM. Train and test periods are shown in Table 1. We use 10% of the training data as a validation set to tune the hyper-parameters. The implementation is done using PyTorch package [30]. Each simulation is run for 200 epochs with a learning rate set to 0.001 and a decaying rate of 0.99 every 100 steps. As for the evaluation metric, we use weighted F1 score which is the harmonic mean of recall and precision.

4.2 Baseline Methods

We compare the performance of DOPE with the following baseline methods.

- **SVM.** In this baseline method, we concatenate the course attributes and students' demographic features as well as weekly click data (i.e., behavioral data) into a single vector and feed it to a support vector machine with radial basis function kernel.
- **LR.** This is similar to SVM except we use logistic regression for classification. The reason for including this baseline is to measure the online course performance prediction problem using a simple classification method without any kernel or non-linearity.
- **DOPE_{FCN}.** This is a variation of DOPE where instead of modeling behavioral data with an LSTM, we use a fully connected network. The reason for including this method is to evaluate the effectiveness of the way we model sequential behavioral data.

We compare DOPE with the baseline methods for the different numbers of weekly click data i.e., 5, 10, 15, and 20 weeks. By doing so, we can measure how effective DOPE is in the early prediction of a student's course performance prediction. We note that 20 weeks is almost half of a course period when there is still adequate time for intervention in the case of prediction as failure.

4.3 Binary Classification

As mentioned before, our dataset includes 4 distinct labels for a student's performance in a course, namely *Distinction*, *Pass*, *Fail*, and *Withdrawn*. In this section, we merge *Distinction* and *Pass* into a single class "Pass" and *Fail* and *Withdrawn* into a single class "Fail" and then perform a binary classification. Figure 5 illustrates the experimental results for all courses. We make the following observations based on the results presented in Figure 5.

- In general, the more weekly click data is introduced, the better we can predict the students' outcomes. DOPE enjoys more of such performance increase as compared to other methods. In particular, as early as 20 weeks from the start of a course (i.e., almost in the middle of a course duration), it can predict student's outcomes with very high performance. This allows teachers or online course administration to take actionable and interventive measures to help students with poor performance.
- DOPE achieves a better performance than DOPE_{FCN}. This shows the fact the LSTM component as a machinery extracting temporal features from click behaviors is necessary and affects the model's predictive power.
- DOPE is shown to be effective for all courses as we can observe it achieves an F1 score of more than 0.8 across all courses when 20 weeks of click data are considered.

4.4 4-class Classification

In this part, we compare the performance of DOPE with baseline methods for a 4-class classification setting whose experimental results are demonstrated in Figure 6. We make the following observations based on the results in Figure 6.

- The observations we made for binary classification hold for 4-class classifications as well. In particular, DOPE still outperforms baseline approaches, more weekly click data is helpful in course outcome prediction, and the LSTM can effectively handle sequential that than simple concatenation followed by a fully connected network model (i.e., DOPE_{FCN}).
- Since more classes are considered, compared to binary classification, the 4-class classification is a harder task. In particular, now *Withdrawn* is considered as a separate class, which might be "conceptually" hard for a model to discern from *Fail*.

4.5 Behavioral Feature Analysis

Since behavioral data (i.e., click data) plays an essential role in determining a student's performance, we conduct a feature analysis experiment investigating the importance of each behavior type. A similar feature analysis has been performed to discover great insights into human behaviors [21]. To this end, we follow an ablation feature analysis where at each time we include one feature type and suppress the rest (setting their values to zero) and then acquire the F1 score from the model. We do this experiment for the binary classification and the case when 20 weeks of click data is included. Figure 7 demonstrates the results and we make the following observations accordingly.

- For all courses, feature type *homepage* is associated with a high F1 score. This seems reasonable since most of the click activity occurs on the main page of the platform interface.
- Interestingly, clicks and activities in *forums* have an influential role in predicting fail or pass of a student in a course. This is in line with previous [15, 31] where they showed that MOOC forum activities correlate with a student's academic performance.

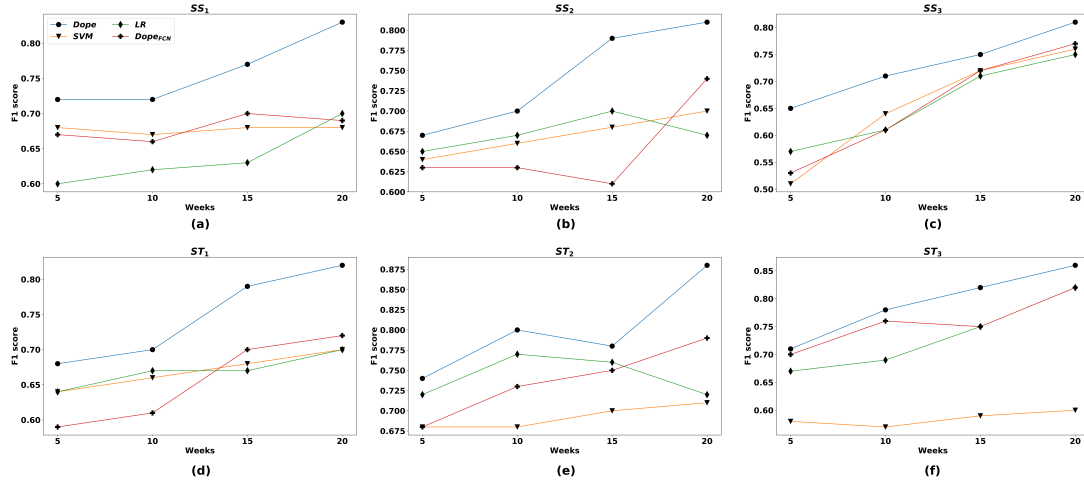

Figure 5: Comparison results for binary classification using four different amounts of included weekly click data.

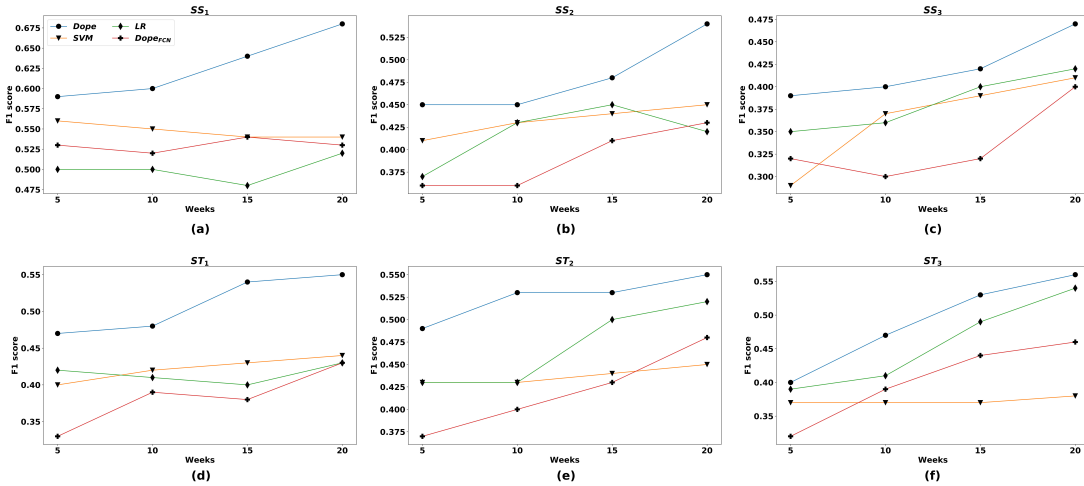

Figure 6: Comparison results for 4-class classification using four different amounts of included weekly click data.

- Unique behavioral importance profile of a course can aid policymakers, administrators and even course interface designers to prepare the course materials in a more informed way. For instance, we can observe that attribute *wiki* is playing an important role in performance prediction of ST_2 while its effect is negligible for other courses. This can be indicative of materials of the course ST_2 to be requiring more wiki access and consequently, the content can be changed accordingly.

Based on the observations above, we can conclude that DOPE encodes behavioral data in an intuitive manner that conforms to previous studies' findings as well.

4.6 Inter-course Outcome Evaluations

Naturally, each course has its own model. However, in this section, we intend to measure inter-course performance evaluation where we train DOPE on one course and test it on another one. Table 2 shows the results. Again, the models are trained for the binary classification and they incorporate 20 weeks of the click data. Also, for the reference, we have included intra-course performance (i.e., the same course for training and test) shown in the diagonal entries of Table 2. Expectedly, when the training course and the test course are the same (i.e., intra-course setting), the

performance is higher. This seems reasonable since clicking patterns are expected for the course in the past (i.e., a part of the training data) and the one in the future (i.e., testing data), and the model can more easily extract such patterns. Although the results for inter-course results are not as good as the ones for intra-course, we still see that the DOPE can effectively achieve reasonable performance. This indicates that the proposed model DOPE can detect salient click and demographic patterns that are transferable from a course to another.

Table 2: Inter-course performance evaluation

	Test course					
	SS_1	SS_2	SS_3	ST_1	ST_2	ST_3
SS_1	0.83	0.78	0.77	0.71	0.8	0.75
SS_2	0.63	0.80	0.58	0.66	0.53	0.66
SS_3	0.64	0.51	0.80	0.45	0.72	0.49
ST_1	0.60	0.79	0.71	0.82	0.47	0.41
ST_2	0.74	0.60	0.56	0.62	0.88	0.49
ST_3	0.79	0.76	0.75	0.70	0.77	0.86

Figure 7: Behavioral feature analysis on different courses. The models are binary classification using 20 weeks of click data.

5. RELATED WORK

In the following, we highlight some of the works focusing on student dropout and performance prediction. In [35], they extracted 27 interpretive features and used logistic regression to predict student persistence prediction. The authors of [32] used probabilistic soft logic to model student survival by constructing probabilistic soft logic rules and associating them. Different from [32] (which mainly considered forum features), in [28] they did not consider forum data, but instead only made use of clickstream data to train their prediction model. More specifically, they used principal component analysis [37] paired with a linear support vector machine [4] for each week. It was in [12] that a more comprehensive approach was taken that used standard classification trees [2] and adaptive boosted trees [1] to construct their two-stage Friedman and Nemenyi procedure for dropout prediction by processing different features such as clickstream-based, forum-based, and assignment-based features. More recently, in [3], the authors studied a hybrid method for dropout prediction by combining both a decision tree [11] and extreme learning machine [18]. In addition to these traditional machine learning methods, some researchers have tried to use different deep learning models for dropout prediction of online courses. In [9] an LSTM was used to deal with the features extracted from students' interaction with lecture videos, forums, quizzes, and problems. [36] explored the potential benefits of employing a fully connected feed-forward neural network for dropout prediction. Different from previous work, [10] proposed a context-aware feature interaction network to incorporate context information of both participants and courses. More specifically, they used an attention-based mechanism for learning activity features. The most similar method to ours is found in [17] where they sought to conduct performance evaluations on students using a graph neural network (GNN), but there are primary differences: (1) they constructed separate small graphs of courses for each student while DOPE constructs a single knowledge graph of historical student course relations; (2) their graph neural network was used to obtain a graph classification for a given student based on that student's specific course graph, while our method uses the relational graph neural network to learn embeddings for both students and courses

from a single large knowledge graph; and (3) DOPE furthermore utilizes an LSTM model to capture a student's rich sequential behavioral data beyond just using static fixed student features.

6. CONCLUSION AND FUTURE WORK

In this paper, we proposed a model for course performance prediction we call it Deep Online Performance Evaluation (DOPE). Our method first represents the online learning system as a knowledge graph, such that we then learn student and course embeddings from historical data using a relational graph neural network. Simultaneously, DOPE utilizes an LSTM for harnessing the student behavior data into a condensed encoding, as the data has a natural inherent sequential form. We tested the proposed model on six courses from the OULAD dataset where the results showed the feasibility of DOPE and that it can predict at-risk students of on-going courses. We also investigated the usefulness of the different types of behavioral features and observed that DOPE encodes the data in an intuitive manner.

In the future, we will first analyze the imbalance and sparse issues of the dataset. One possible way to alleviate the sparsity would be through a network alignment [6] of multiple MOOC datasets represented as knowledge graphs or connecting student behavior data from social media for better predictions in online education [22]. Also, we will investigate more advanced ways of handling behavioral data. For example, investigating better ways to use "subpage" clicks beyond a simple aggregation that ignores separating the multiple different "subpages". In addition, we plan to apply our framework to the traditional education system aiming at identifying similarities and differences between online and traditional course performance prediction, since we believe this to be highly important in improving online learning systems.

ABSTRACT

Imagine a student using an intelligent tutoring system. A researcher records the correctness and time of each of your attempts at solving a math problem, nothing more. With no names, no birth dates, no connections to the school, you would think it impossible to track the answers back to the class. Yet, class sections have been identified with no more data than this. This paper recounts shocking episodes where educational data was used to re-identify individual students, build profiles on students, and commit fraud. We look at the ethical principles that underlie privacy as it relates to research data, and discuss ethical issues in data mining relating to social networks and big data. We explore four major types of data used in EDM: (i) clickstream data, (ii) student-interaction data, (iii) evaluative data, and (iv) demographic data. Each type of data can be harmful if disclosed in particular contexts, even if all personally identifiable information is removed. We consider laws and legal precedents controlling access to student data in the United States and the European Union. This paper concludes by describing some practical situations in EDM and suggesting privacy policies that satisfy the ethical concerns raised earlier in the paper.

Keywords

Privacy, anonymization, de-identification, ethics, educational data mining

1. OUR DATA ARE MORE THAN VALUABLE

Educational data mining (EDM) analyzes student data from Learning Management Systems (LMSs) and stand-alone educational applications. Educational technology (EdTech) vendors use student data to analyze student performance, improve student models, and discover opportunities to boost

learning. Any EdTech data breach or unjustified student tracking infringes student privacy, generates huge controversy, and produces big headlines. The ability to create auxiliary connections with other known information makes data valuable to both hackers and researchers. EDM researchers need to understand privacy risks raised by sensitive data.

1.1 Privacy risks of educational data breaches

One of the biggest leaks of student data was the Edmodo data breach. Edmodo is an EdTech company that provides coaching tools and a collaborative platform for K-12 students and teachers to communicate about course content, quizzes and assignments. The breach involved 11.7 gigabytes of data and over 77 million uniquely identifiable users, exposing at least 50 million usernames and 29 million emails. Edmodo did acknowledge the breach's occurrence, but by that time data was being sold by the hackers on the black market [9]. The breach was important, not because of the inherent value of the data itself, but rather because of how the data could be connected with auxiliary datasets. Having a list of hashed passwords is not useful; knowing that people tend to reuse passwords exposes other systems to greater risk. Leaking names and email addresses also left the students at greater risk of identification or additional tracking.

Since other breaches or publicly available datasets reveal personal information such as addresses or ethnicity, they can be cross-referenced to the leaked data to reveal a more complete identity. Companies shy away from controversy when it places their product or service at risk, and victims tend to not come forward, lest they sacrifice their privacy. It is important to take these breaches seriously, as any data leaked by research projects or products has more value now than before this large data breach.

Let's examine other educational data breaches. At Torrey Pines High School in San Diego, California, the online grading system was hacked to alter students' grades and transcripts [17]. This incident highlights risks like grade changes by unauthorized parties. In Montgomery County, Maryland, a student performed a brute-force attack on Naviance, an online platform for college and career readiness. The attack exposed sensitive data from 5962 accounts, including names,

Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 451 - 459

addresses, phone numbers, GPA, and SAT scores [12], that students trust will remain private and protected.

In the last two years, Chinese media have reported several cases where students' personal information, including their national identity card number, was stolen or leaked. Companies then used students' identities as phantom employees for tax fraud [7, 8]. One of the saddest cases related to an educational data breach occurred in 2016. After the national college entrance exam, a criminal group hacked a local university application system and acquired students' personal information, including phone numbers. The perpetrators posed as financial-aid officers then contacted students, asking them to transfer money into specified accounts before their financial aid could be delivered. One student contacted, Yuyu Xu, died from sudden cardiac arrest after discovering that it was a fraud [6].

1.2 De-identification is not enough

In a 2005 contest to devise better movie-recommendation systems, Netflix released 10 million movie rankings by 500,000 customers after removing all direct customer-related information. Two University of Texas researchers showed that simple anonymization fails to preserve privacy; researchers connected anonymized Netflix dataset entries with distinct users in the Internal Movie Database [43]. Similar risks are present in anonymized datasets used for EDM research.

Another compromise of anonymized data occurred when the "Tastes, Ties, and Time" (T3) project released de-identified Facebook profile data. All personally identifiable data was removed, such as names, email addresses, university name, and names of friends. However, the dataset's associated code book provided a list of students' majors and state or country of origin. Within a couple of days, researchers at University of North Carolina at Chapel Hill and University of Wisconsin-Milwaukee identified the "anonymous northeastern university" as Harvard. This raised significant privacy concerns as research assistants at Harvard University who were "friends" with some students in question, had deeper access to profiles than the general public. Both the Harvard IRB and Facebook had approved the project [69].

In one case, researchers collected clickstream data from multiple classrooms across the country instead of personally identifiable information (PII) or demographic data about an individual student. They created clusters of students from log files, recording time and correctness of students' responses. These clusters were enough to identify classes of gifted students and extract demographic data about student groups [67]. When one cluster missed a day's worth of work, the researchers cross-referenced potential classrooms with announcements of a field trip. This resulted in a single classroom being identified using only anonymized data.

Common de-identification techniques include: *Anonymization*, where all PII is simply removed from the dataset; *hashing*, where multiple fields (e.g., last name and email address) are hashed into a single value, and replace the original fields in the record; *swapping*, where some field, such as a name, is switched to apply to someone else's record; and *noising*, where data values are perturbed (changed) in some way [37].

These common de-identification techniques can have adverse effects on data quality [14]. Protecting students' privacy by removing re-identifiable attributes from data can reduce the data's utility for analysis [67]. Noising data can diminish performances of supervised learning models [44]. Despite not changing aggregations, swapping has similar effects [41]. Thus, it is crucial to balance privacy with utility. Ohm (2009) warns that "the utility and privacy of data are linked, and so long as data is useful, even in the slightest, then it is also potentially re-identifiable" [47].

Building profiles for targeted advertising also endangers student data privacy. Data can be collected by amassing emails or system interactions, like websites visited. Students can be identified and targeted on the basis of their answering patterns, e.g., what questions they answered correctly. Google, which provides the educational content platform GSuite for Education, has been alleged to have built personalized profiles of students based on their GSuite interactions, and to have scanned students' emails to target advertising [23, 28]. Selling the data to third-party vendors without consent would raise severe ethical questions.

In these cases, students' identities and information were used or revealed without explicit permission, undermining the idea of consent. Although releasing someone's homework grade or test score seems trivial, researchers need clear understanding of what constitutes legal and ethical usage of student data so students remain protected while the EDM research efforts continue into noble frontiers.

2. ETHICAL PRINCIPLES RELATING TO EDUCATIONAL RESEARCH DATA

Deciding what constitutes "responsible use" bridges research ethics and other ethics subfields. Each field emphasizes different aspects of the research process. As with any ethical discussion, clarifications of these terms and new realizations of technologies causes these principles to evolve to reflect the state of EDM research. Several analyses have looked at key principles in a more abstract form [48, 51, 59], but these works are too broad to answer specific questions. This paper seeks to highlight key principles from each subfield and applications to specific areas of EDM research.

2.1 Research ethics

Much of the literature on research ethics derives from the Nuremberg Code [34], the Helsinki Declaration [2], and the Belmont Report [15, 35, 65]. But the Belmont report lacks specifics on internet-mediated research [1]. The Menlo Report [4] extends principles from the Belmont Report to computing centric research. It adopts three principles found within the original Belmont Report, and adds a new fourth principle, respect for law and public interest.

2.1.1 Respect for Persons

The Belmont Report establishes the principle of *respect for persons* through two key frames: treating individuals as autonomous agents and entitling individuals to protections [65]. The Menlo Report adds consideration of computer systems and data that directly impact people who are typically not research subjects themselves [4]. This impacts the concept of informed consent. Informed consent comprises three

concepts: notice, comprehension and voluntariness [4]. For EDM research, consent documents must not promise improved service or instruction in return for participation; this could be interpreted as coercion. This is relevant to intelligent tutoring systems (ITSs)—students unwilling to allow an ITS to use their data for research purposes should not thereby be academically disadvantaged.

The Menlo Report reiterates consent from one person does not constitute consent from all members of their group, and consent given for one research purpose should not be considered valid for different purposes. Since data subjects are co-owners of educational data [40], concepts such as downstream consent [13] should be considered for applications like educational data warehouses. To further protect individuals, the Menlo Report suggests de-identification of data. De-identified data can fit into the special regulatory category of “pre-existing public data,” which affords more opportunity for exemptions granted by research ethics boards.

2.1.2 Beneficence

For identifying of potential benefits and harms, the Menlo Report targets systems assurance (confidentiality, availability, integrity) and individual and organizational privacy [4]. Within EDM, this means identifying likely flaws or biases in ITSs prior to deployment or introducing protections for model inference and model inversion attacks [20, 52, 56, 58].

When collection or storage of high-risk data is necessary, the Menlo Report suggests to destroy data once past the retention period of scientific reproducibility, which is commonly 3 years at minimum [11, 46]. A tension exists between data retention for research replication and ensuring privacy of data subjects, which will be discussed further in section 3.2. Utilizing data aggregations prevents the need to store sensitive information that could tie back to a specific student or class.

2.1.3 Justice

With regard to *justice*, the Menlo Report declares research should not target specific people or groups based on attributes such as technical competency or personal demographics [4]. For EDM researchers creating some model or product, this discourages using convenience samples such as classrooms the researcher worked with previously. Instead, research should target classrooms or groups of students where the potential intervention provides the most benefit. Using prior data providing an accurate cross-section of the larger community being studied is more favorable than potentially excluding future groups from participation.

The Menlo Report compares actively excluding groups out of prejudice and actively including entities willing to cooperate and consent. Including entities demonstrates the principles of Respect for Persons and Beneficence outlined earlier. Specifically targeting subjects through coercion undermines legitimate research and violates the principle of Justice [4].

2.1.4 Respect for Law and Public Interest

The Belmont Report implicitly classifies respect for the law and greater public interest as an aspect of Beneficence. The Menlo Report considers it a fourth principle with two applications: compliance and transparency/accountability [4].

These provide some assurance of public good whenever identifying stakeholders is difficult or impossible. Lacking transparency and accountability weakens current research projects at hand and learning analytics research credibility as a whole.

Within EDM research, compliance, transparency, and accountability all require researchers to understand relevant laws in their jurisdictions. Researchers are culpable for being up-to-date on laws and regulations where they perform research. Transparency means releasing source code or clearly communicating what information is collected and what computations are performed. Transparency is in the interest of research subjects, the beneficiaries of research, and research ethics boards as they audit projects where necessary.

2.2 Social networks and ethics

With a growing level of research incorporating data directly from social networks, EDM must consider the various ethical principles guiding online behaviors. The disconnect of individuals from online identities must be considered while using social networking data and its derivations. Seeing incomplete aspects of an individual’s personal life through their social network lens affects and alters the perception of them.

Users curate their identities in an online setting [61]. Some students may only use social network services to communicate within specific spheres like family, workplaces, or friends. Students’ online actions and behaviors may not truly reflect themselves as learners, but as reflections of the sphere they are in. Social networks have distinct group dynamics, similar to the real world, further complicating the trustworthiness profiles provide as a snapshot of the student. In theory, social network users should be exposed to opinions of diverse worldwide users, but in practice, views and news feed algorithms constrict types of content users see [50]. In online settings, users tend to subjugate their identities to the group identity they participate in (e.g., student, liberal, conservative, Christian, Muslim), in order to conform to the group [50]. With these considerations in mind, this may devalue the student’s social network presence to the point where social network data may lack enough integrity to be used.

Some broad concerns with using social network data include availability of users’ data to third parties to create marketing profiles, using data mining applications without their knowledge or consent, surveillance by law enforcement, or having third party applications collect and publish user data without notification [66]. Social networking services provide privacy controls for users; however, failure to understand implications of sharing information on a social networking service results in decreased privacy for users in relation to outside actors such as researchers [5].

When releasing de-identified Facebook account data as part of the T3 project, researchers placed limited concern on research ethics and students’ privacy. Utilizing data was not the problem; failing to recognize how collection methods affected privacy is the issue. While acquiring profile data, researchers could have broader access than originally intended by the profile owner. This happens if researchers have prior connections through memberships in their organization or having mutual connections to the profiles. If research combines educational and social networking data but disrespects

privacy standards laid out by the student on platforms like Facebook (or if researchers fail to seek further consent from students about using their social network data), then this breaches the student's overall privacy [69].

2.3 Big-data ethics

Data possesses properties distinguishing itself from other advanced forms of technology, not limited to: its regarding as an aspect of societal infrastructure; its interconnectedness; its dynamic nature for discovery beyond original purpose; its real-time analysis and decision-making possibilities; its usability regardless of where, when, and for what purpose it was collected; its reusability for unexpected purposes to reveal unexpected information (the core purpose of data mining); its intrusiveness due to storing data about individuals in multiple databases; its ownership issues, especially in education settings [26, 40]. Each individual datum is useless without context and associated metadata. By this construction, value added to data provides its potential for misuse. In EDM, positive outcomes for students come from discrete products or further insight on learning motivations and processes; this does not exclude potential misuse by researchers.

Although this paper will not discuss algorithmic fairness in detail, the concept applies in big data ethics. Many practices classify or regress individual experiences into common baselines based on socioeconomic status, race, ethnicity, or gender without explanatory data. Division into classification groups and averaging metrics stereotypes students. Unchecked stereotyping could rehash old prejudices that negatively affect research itself. The lack of care to blindly use basic classification groups can be extreme enough to break the principle of “doing good work” [26]. Instead, research should favor groups created by methods like Topological Data Analysis [22] and other Bayesian models that cluster outside of traditional demographic groupings.

2.4 Ethical uses of specific educational data

There are four kinds of data commonly used in EDM that have further ethical concerns for researchers: clickstream, student interaction, evaluative, and demographic data.

2.4.1 Clickstream data

At minimum, clickstream data provides information that some generic user initiated an interaction at a given time. Although relatively safe on its own, a classroom worth of students generating clicks can reveal the location of the classroom, especially if the classroom functions on a daily or weekly routine. Studies have already shown tracking IP addresses to reveal geolocation [38], which shows the potential for this to be done for clickstream data as well. Utilizing this aspect of clickstream data allowed Yacobson et al. to identify a gifted student classroom from a completely anonymized dataset of over 500 students after clustering time of clicks and correctness of answers. Once a class deviated from the schedule due to a field trip, researchers then identified the school and classroom in question [67].

2.4.2 Student interaction data

Student interaction data includes peer assessments, online discussion forums, and team-member evaluations—data with a clear writer-respondent relationship. These interactions

directly reflect the respondent's viewpoints, which may violate privacy if shared outside of the student-teacher relationship when they cast aspersions on the student. If negative comments are given about the writer, and that information somehow leaves the model or is revealed to an outside source, this could affect student's relationships and future prospects. Similarly, sharing class forums regarding sensitive subjects like sexuality to wider audiences is not proper since this could potentially identify and harm a student.

2.4.3 Evaluative data

Evaluative data references include grades and other inputs to predictive analytics models. In educational settings, clear benefits to predictive models include quality assurance and improvement of instruction, tracking and predicting retention rates, and enabling the development of adaptive learning [3, 57]. These same models could influence later interactions between students and instructors, thus affecting the relationship and trust—a proven factor in the academic success of students [19, 21, 39, 53]. For example, if a predictive model flags a student for high potential of failure and dropout from a course, the instructor may focus interventions on that student. This could overcome other reasons for a student's poorer performance, thus remedying symptoms rather than determining underlying causes for the struggles.

2.4.4 Demographic data

Many studies looked at how simple demographics can identify a non-negligible number of individuals [24, 60]. Student demographic data can be combined with other data to infer identities of students. In the T3 project, student Facebook data identified many individuals as being the only Harvard freshman student from a certain state or country. Identifying an exact student is possible when combining news announcements or other university materials [49]. With the growing number of data breaches like the Edmodo case and the noted intrusiveness of big data due to an individual's membership in many databases, this leads to a risk that often goes unnoticed for smaller research applications. For EDM researchers, having researchers redact some demographic information, when not integral to research, may assist students in controlling their information and privacy.

In summary, it is vital to see how ethics does not adhere to data itself; the researchers themselves and how the data are used carries significant ethical implications. Understanding the scope of data collection, storage, and usage ultimately impacts the ethics of research and benefits for learners.

3. LAWS AND LEGAL PRECEDENTS

Legal regimes vary substantially throughout the world; an exhaustive comparison is beyond the scope of this paper. Legal frameworks for educational data exist in other countries, but their impacts are less clear [18, 62, 63, 64]. We focus on the two largest EDM research communities: the United States and the European Union.

3.1 United States

In the United States, the most relevant legislation is the Family Educational Rights and Privacy Act (FERPA). Enacted in 1974 after widespread concern about intrusive psychological testing of students, FERPA defined the circum-

stances which allow schools to release a student’s “education records” to outsiders (including EDM researchers). Personally identifiable information (PII) about a student must not be disclosed unless the student, or the parents if the student is under 18 years old, give their prior consent. The law applies to all schools that receive funds under a program administered by the US Department of Education. In practice, this includes virtually all colleges and universities, as well as public (but not private) elementary and secondary schools.

Under the law, PII includes students’ names, names of parents and family members, Social Security or student ID numbers, biometric records, and other indirect identifiers including date or place of birth and mother’s maiden name. It also includes “[o]ther information that, alone or in combination, is linked or linkable to a specific student that would allow a reasonable person in the school community, who does not have personal knowledge of the relevant circumstances, to identify the student with reasonable certainty.”

This raises two main issues: What is an education record, and what does the “other information” mentioned above include? For example, does clickstream data collected by an ITS count as an “education record”? The most relevant court case is *Owasso v. Falvo* (534 US 426 (2002)). This case arose in Oklahoma, when a teacher had students peer-grade each other’s papers. Papers were collected from students and passed out to other students. The teacher called out the correct answers, and each student would mark answers on the paper in front of them as correct or incorrect. The school district was sued by the a student’s mother who said that her son, who had not scored very well, had been embarrassed when a fellow student called out his score.

The case eventually reached the US Supreme Court, which ruled unanimously that peer grades did not constitute “educational records.” FERPA established a two-part test to determine what was an educational record: (i) The material must “directly relate to the student” and (ii) must be maintained by the institution or an individual acting on the institution’s behalf. The decision turned on the test’s second part. The court ruled grades were not “maintained by .. an individual acting on behalf of the institution,” at least until entered in the teacher’s gradebook. The court did not rule whether teachers’ gradebooks are an educational record.

The *Owasso* decision seems to imply that FERPA does not prevent the disclosure of student classwork and homework to outside researchers, except possibly if outsiders can use it to discover students’ grades for the assignment. In general, data from web-based participatory learning tools is not covered under FERPA [27]. Note that this is a legal judgment, not an ethical one, since disclosure of student information from some such tools may allow re-identification by others.

However, one clause in FERPA implies this situation may not last. The clause on linkable information implies that what constitutes PII changes as technology changes [68]. As datasets become higher dimensional, the possibility of using an auxiliary dataset to re-identify people grows [42]. Thus, every researcher releasing a de-identified dataset should be familiar with the growing risks.

A distinction should also be made between datasets used for analytics and datasets used for intervention [30]. A researcher simply analyzing effects of some practice or tool on student learning has little need to track individual identities. If the dataset is used for intervention—to improve experiences of particular students—obviously the students’ identities must be preserved. In this case, FERPA may still apply, since neither the law nor *Owasso v. Falvo* clearly delineates what kind of research data constitutes an “educational record.” Fortunately, interventions are often in house; data of this nature would rarely be important to outside researchers. However, if interventions are with students in other institutions, it would be worth seeking legal guidance.

3.2 European Union

The European Union adopted the General Data Protection Regulation (GDPR) in April 2016, which took effect in May 2018. GDPR applies to processing “personal data” tied to an identifiable person. For practical purposes, this seemingly is the same as FERPA [45] (except GDPR also applies outside educational contexts). According to GDPR [33],

[A]n identifiable natural person is one who can be identified, directly or indirectly, in particular by reference to an identifier such as a name, an identification number, location data, an on-line identifier or to one or more factors specific to the physical, physiological, genetic, mental, economic, cultural or social identity of that natural person.

This is subject to the same uncertainties as FERPA. One place where the two laws differ is in the EU, the subject must consent to use of their personal data: the researcher must secure “a clear affirmative act establishing a freely given, specific, informed and unambiguous indication of the data subject’s agreement to the processing of personal data relating to him or her ... Silence, pre-ticked boxes or inactivity should not ... constitute consent [recital 32]” [29].

Another consideration is the GDPR’s signature provision: the “right to be forgotten.” If the subject of the data withdraws consent, the data must be erased. The data must also be erased when no longer needed for the purpose (e.g., research) that it was collected for [29].

4. IMPLICATIONS OF EDM RESEARCH

Having discussed privacy risks, ethical considerations, and legal risks for EDM researchers, we now examine current privacy concerns and work needed in the near future. Through correspondence with EDM 2019 researchers and reflection on our own research, we identify the following areas as requiring attention to the principles and risks established earlier.

4.1 Crawling learners’ data outside a platform

Though most EDM researchers use data generated *within* educational platforms/systems such as MOOCs/ITSs, sometimes it can be tempting to acquire data on learners *beyond* a specific tool and beyond the course duration. When researchers use the learners’ information to access their data on social web platforms after they have finished a MOOC,

for example, more research questions can be answered, such as “does displaying MOOC certificates have an impact on learners’ career paths?” Chen et al. traced the learners’ profile data overtime on Gravatar, StackExchange, GitHub, Twitter, and LinkedIn after the MOOCs to investigate the impact of MOOCs in the long-term [10]. Chen et al. used data from 18 MOOCs and reported they could reliably identify the highest of 42% of the learners in a MOOC on social web platforms. The MOOC data (from edX) they started with had the usernames, full names, email addresses. Therefore, it is not a surprise that a high percentage of learners can be identified. However, crawling data of learners on five social-media platforms several years after they have finished a MOOC does bring up privacy concerns.

Arguably, learners’ profile and posts are the data available to the public, but EDM researchers are able to join learners’ data from an educational platform with learners’ data on social web platforms, which may give researchers too much power in mining learners’ data after they have finished their learning. Considering the learners’ additional data can potentially be crawled, the sharing and reusing learners’ data should be backed with appropriate legal agreements. For example, Yacobson et al. suggested to “ban linking application data with external data sources” [67].

4.2 Community consensus on learners’ privacy

Researchers need data with high utility, but the effort to anonymize data hurts this. In other words, keeping datasets of high utility and high privacy level concurrently is hard. De-identification protects learners’ privacy, but too strict de-identification can negatively affect analysis [37].

Besides, there is always a risk that de-identified data can be re-identified, especially if de-identification is done in a shallow approach (e.g., by removing learners’ full names, emails). The reason is that learners’ personal “footprints” also reside in their artifacts and interaction patterns with the educational platform. Yacobson et al. presented an example where they re-identified the school that the learners were in based on de-identified clickstream logs [67]. Similarly, being teaching software engineering long enough, the paper’s fourth author would argue it is possible to tell learners’ demographic characteristics by reading their code.

The tension between usefulness and anonymity of the data is not likely to be solved by legislation. Hoel et al. analyzed three different privacy frameworks in selected countries [32] and presented clear differences on value focuses – e.g., the European framework focuses on individuals and the Asian privacy framework focuses on the organizations. Though we have observed that the legislation in one region can have an influence on future legislations in other countries [25], the time for those data protection legislations to “converge” (if possible) may take a long time.

As a result, the best short-term result we can have could be a community consensus in the EDM and LA (Learning Analytics) research communities. In addition, when an anonymized dataset is posted/shared, we advocate that researchers limit the *additional information* provided about the student population to reduce the risk of re-identification. For example, a dataset generated by “graduate Algorithms

II students in an R2 university on the east coast of the U.S.” is more likely to be re-identified than a dataset generated by “students in a graduate Algorithms course”.

4.3 A protocol for configuring privacy policies

A common definition for privacy is the POQ framework: “some person or persons P, some domain of information O, and some other person or persons Q, such that P has privacy regarding O with respect to Q” [54]. For example, Alice (P) took an online course with sponsorship from her employer (Q). Her course completion status (O) is accessible by her employer; in other words, P does not have privacy regarding to O with respect to Q. This privacy policy may not be configurable by the learner based on the privacy policy of some online learning platform, for example, edX [16].

Though the POQ framework can serve as a basis for privacy policies, it leaves out some essential components [55]. The privacy protocol helps learners manage privacy in any learning environment. Hoel and Chen suggest the policy should achieve privacy by negotiating “with each student” [31]. Certain components should be added to the POQ framework to extend it for educational service providers.

First, the lifespan of privacy policies should be added. To follow the example above, when Alice leaves the current company, should the former employer still have access to Alice’s records on edX? Besides, the purpose of the planned usage of the data (e.g., to gain generalized knowledge of the student population, to predict individual student’s success in a course, etc.) should be part of the protocol. Educational data can be “justifiably collected and analyzed for one educational context, but not another” [55]. Moreover, privacy protocols should stipulate that learners can access data analysis results based on their data. It is common for researchers to use students’ data to predict student success (or failure) [36]. When there is a prediction, not all the students are willing to see this information, and some educators may not be ready to share this information with students.

5. CONCLUSION

Overall, it does not seem likely that legislation related to educational-data privacy in different countries will be harmonized in the near future. Many datasets from education settings have re-identification risk, even after personal information is removed. Therefore, the research community has to move forward and establish a certain level of consensus to discourage research projects that are of high ethical risk and relatively low research value. Seeking excessive personal data on learners from the social web could be one of them. EDM researchers and third-party tool providers should take responsibility to foster a trusting relationship between learner and teacher, and learner and institution.

Like any survey paper, this work is not specific enough to guide each and every research action, and it will not cover all legislation relevant to an EDM researcher. Within a couple of years, most of this information will be supplanted by new legislation, research paradigms, innovative technologies, and research by the exciting generation of upcoming EDM researchers. Being aware of and vigilant against all possible risks will protect the interests of the EDM research’s most important stakeholders: learners, students and teachers.

ABSTRACT

Recommending courses to students is a fundamental and also challenging issue in the traditional university environment. Not exactly like course recommendation in MOOCs, the selection and recommendation for higher education is a non-trivial task as it depends on many factors that students need to consider. Although many studies on this topic have been proposed, most of them only focus either on historical course enrollment data or on models of predicting course outcomes to give recommendation results, regardless of multiple reasons behind course selection behavior. To address such a challenge, we first conduct a survey to show the underlying characteristic of the course selection of university students. According to the survey results, we propose a hybrid course recommendation framework based on multiple features. Our experimental result illustrates that our method outperforms other approaches. Also, our framework is easier to interpret, scrutinize, and explain than conventional black-box methods for course recommendation.

Keywords

Educational Data Mining; Recommender Systems; University Environments

1. INTRODUCTION

Course selection in university is a crucial and challenging problem that students have to face. It is difficult to decide which courses they should take because there are a large number of courses opened each semester and students have to spend a lot of time exploring those courses. Moreover, the decisions they make shape their future in ways they may not be able to conceive in advance.

We collected a dataset during 2015 and 2018 from our university to gain a better understanding of the elective course enrollment patterns. Figure 1(a) presents the distribution of the enrolled course number of students on the left and the distribution of the popularity for each course of our university on the right. There are hundreds of elective courses offered by the university while averagely students only select a few of them to satisfy the requirements for their degree program. Figure 1(b) shows the distribution of the enrolled courses for each semester. We can also see that students may take courses in the first two years mostly (semester1~semester4), because they may potentially be busy with an internship or finding jobs in the third and fourth year.

Boxuan Ma, Yuta Taniguchi and Shinichi Konomi "Course Recommendation for University Environment" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 460 - 466

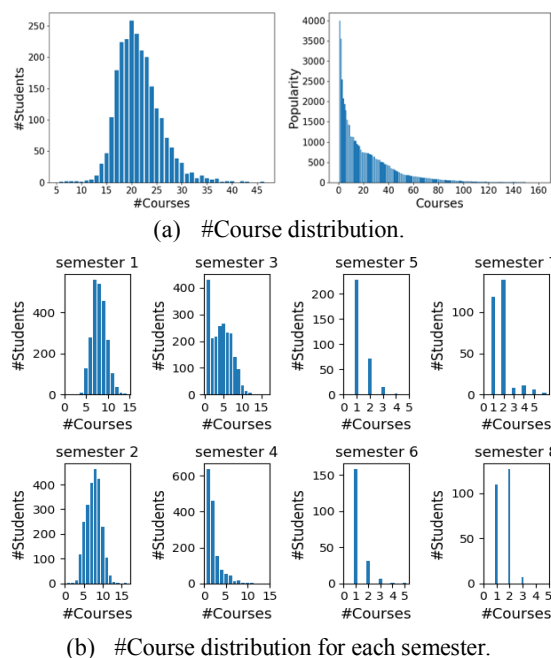

Figure 1. Distribution of courses.

From the discussion above, a safe conclusion could be drawn that due to a large number of available but unfamiliar courses, course selection is a critical activity for students.

With the increasing amount of available data about undergraduate students and their enrollment information, data-driven methods supporting decision making have gained importance to empower student choices and scale advice to large cohorts [14]. Many relevant studies on course recommendation focus on online learning platforms such as MOOCs. Other studies on course recommendation use datasets collected in physical university environments, however, they rely on approaches that are similar to the ones used in recommending MOOC courses without fully considering the different reasons involved in course selection process in physically-based university environments.

In fact, course recommendation for higher education can be more "messy and unorganized" [1] as it depends on many factors that students need to concern. Intuitively, the reasons behind course selection are manifold. Likewise, students who enrolled in the same course may have completely different orientations based on their own reasons, which serves as different criteria for course selection [34]. It inspires us to try to find more useful features for the recommendation.

To make the point clear, a survey is conducted on 81 students in our university to better understand student perceptions and attitudes for their course selection process. [10] Figure 2 shows the main underlying reasons for their course selection.

Figure 2. The distribution of main reasons for course selection.

(1) Interest

As Figure 2 shows, the overall most important factor was students' interest and it is often taken as a main contributing factor to the recommendation. However, students may not choose courses based purely on their interest in the university environment. It is expected that students will be more inclined to choose courses that do not require too much effort or difficulty. For example, some students would not enroll in a course which contains contents they are interested in, they just choose the course that allows them to get credits easily.

(2) High-Grade

Improperly selecting courses would seriously affect the students' course achievements, which enforces students to drop out [12]. Getting relatively high grades for students is another factor influences student's choice especially for successful students. Some students even prefer to choose what they perceived would be an easier course for fear that a tougher course might lower their GPA.

(3) Learning goal and career plan

It is natural to recommend courses that align with student's learning goals and career plans as students consider the usefulness of courses as an important factor in their course selection process. However, first-year students may lack learning goals and career planning for the future, and the choice of courses is aimless. Also, student interest and goal can change as they explore and discover something meaningful on and off campus.

(4) Social Aspect

Social factor also plays a part in the course selection process. For example, some students prefer to enroll in a course with their friends or classmates together. Potts et.al [21] conclude that the risk of social isolation is a problem in the learning process especially for first-year students at university, who have difficulty navigating their new academic and environment. Tinto [22] concludes that participation in a collaborative learning group encourages student's attendance and class participation. Therefore, the classmates or friends based social links could be important information in course recommendation.

(5) Popularity

As shown in Figure 1(a), the long-tail distribution of course popularity indicates that students are more motivated to choose popular courses as their first choice. However, the popular courses will be filled up quickly while others will not be selected by students frequently.

In summary, all these discussions above indicate that there are complex constraints and contexts that have to be considered together to balance all those factors above, made more difficult by the multiple objectives that students want to maximize and risks they want to hedge against. For example, choosing challenging courses of value while maintaining a high GPA [16]. This suggests

that recommendations that are aimed only at one or a few factors are likely not enough to help the students.

To address these challenges which have not been well explored in the research community, we propose our hybrid course recommendation framework, which incorporates different criteria in a modular way. Moreover, in our approach selection criteria can further be prioritized by the student. We believe that weaving those criteria could increase the usability of our recommendations compared to previous work focusing only on one of the two. Also, our framework is very efficient and easy to interpret.

2. RELATED WORK

2.1 Course selection

Some work has been done on analyzing the college students' course selection. Morsy and Karypis [23] investigated how the student's academic level when they take different courses, relate to their graduation GPA and time to degree. This study suggests that course recommendation approaches could use this information to better assist students towards academic success, by graduating on-time with high GPA. Also, understanding students' reasons for enrolling in a course provides key information for recommending courses and improving students' learning experiences [24-27].

Additionally, there is still a lack of study on the factors that influence students' course selection in university and how the course selection would impact the students' educational achievement.

2.2 Personalized Course Recommendation

Various approaches have been used in applications for course recommendation by learning from historical enrollment data [32, 33].

Content-based filtering approaches recommend a course to a student by considering the content of the course and clustering course and student into groups to gain similarity between them [2,3]. Collaborative filtering approaches recommend a course to a student by investigating student's similarity with the student's historical data in a system and predict the course that the student would be interested in [4-6]. Association rules based on frequent patterns are used to discover interesting relations that describe previous course selections from students [8,9]. Recently, other methods including sequence discovery and representation learning have been used in this domain [11,19,20]. However, those systems often behave like a "black box", i.e., recommendations are presented to the users, but the rationale for selecting recommendations is often not explained to end-users.

2.3 Grade Prediction

While some researchers have focused on between-course enrollment data, others have focused on models of predicting grades in future courses [13-6]. Based on what courses they previously took and how well they performed in them, the predicted grades give an estimation of how well students are prepared for future courses, then recommending courses to students that will help them to get relatively high grades [18,28,29,31].

However, these methods can be prone to recommending relatively easier courses in which students usually get high grades [17]. In addition, there are some students who like challenge difficult courses if they are interested in or think it is helpful for their future career, for those students, the grade prediction based recommendations are not enough.

Despite the significant success of various course recommendations, constraints on the number of student preferences in the university environment resulting in inflexibility where a student's requirements do not align perfectly with those built into the system. In contrast to the aforementioned approaches, our model combines the concerns of performance and interest together. Also, it has the benefit of allowing for a custom weighting of those components, as well as the increased explanatory value of the model itself.

3. PROPOSED METHOD

We first give the definition of our recommendation problem in Section 3.1. Then we propose our hybrid course recommendation framework with three subsections introducing our Interest-based Score, Timing-based Score, and Grade-based Score in detail. Finally, those different scores are used in our course recommendation algorithm introduced in Section 3.3.

Figure 3. Overview of the proposed course recommendation.

3.1 Problem Formulation

Like every classic recommendation task, there are two basic elements *user* and *item* in our course recommendation task, where a user represents a student and an item represents a course. We use S to denote a set of students and C to denote a set of courses. Each $s \in S$ has enrolled some courses denoted by $C_s \subseteq C$ and each $c \in C$ has its enrollment set denoted by $S_c \subseteq S$. Let T denote a set of all available semesters, and t to denote a specific semester. Generally, there are 8 semesters for 4 academic years degree program. Let G denote a set of grades that student could get, and each $g \in G$ denote a specific grade that student obtained for a course. Let $E = \{(s, c, g, t) | s \in S, c \in C_s, g \in G, t \in T\}$ be the set of all enrollment relations, which means student s enrolled in course c in semester t , and got the final grade g .

Given enough students enrollment data (S, C, E) , our goal is recommending courses to a specific student s which are not in C_s for next semester.

3.2 Framework

According to the result of the survey shown in Section 1, students may concern different factors while they choose courses. Inspired by that, we propose our hybrid course recommendation framework that considers student interest, the timing of taking the course and the predicted grade of the student together. Figure 3 shows the overview of the proposed course recommendation.

For each pair of student and course (s, c) , we need to understand how suitable the course is for the specific student. We use three different aspects to calculate the $Score(s, c)$ for each pair of student and course:

(i) *Interest based Score (IS)*, which is to measure how interesting the course is for a specific student. (ii)

Timing based Score (TS), which is to measure how suitable students enroll in the course at a specific time (semester) since different courses may have different suitable time periods. (iii) *Grade based Score (GS)*, which is to predict students' performance for the course.

We propose our approaches to estimate IS , TS and GS , respectively. Then, they are fused by a student-specific weight parameter as the $Score(s, c, t)$. Once all of the $Score(s, c, t)$ have been computed, the k courses with the highest score are selected.

3.2.1 Interest-based Score

Let s and c be a student and a course, respectively, the goal of interest score estimation is to calculate $IS(s, c)$.

In our framework, we extract user interest from student historical enrollment behaviors. Since each course of university belongs to a category, let $CATE$ denote the set of all categories, $cate$ to denote a specific category, then $CATE = \{cate_1, cate_2, \dots, cate_{|CATE|}\}$. We think that there is a strong relationship between student interest and course categories. For instance, a student frequently enrolls in courses which belong to "Computer Science" may imply that the student has an interest in this category or he may have personal learning goal in this domain. Hence, it is appropriate to recommend the student the courses such as "Python Programming" and "Data science".

For a student s , the idea is to count the number of courses that he enrolled in and belongs to a category, i.e., $Num(s, cate)$. Then, all of the values are normalized as the preference score from 0 to 1, denoted as $p(s, cate)$, which is defined as equation (1).

$$p(s, cate) = \frac{Num(s, cate)}{\max_{cate' \in CATE} (Num(s, cate'))} \quad (1)$$

For a student s , the preference vector \mathbf{P}_s , is obtained by the preference score of each category, which is defined as equation (2).

$$\mathbf{P}_s = (p(s, cate_1), p(s, cate_2), \dots, p(s, cate_{|CATE|})) \quad (2)$$

We can further use \mathbf{P}_s to calculate the similarity between student s and other students. Let s_i and s_j be two students, the similarity between s_i and s_j can be measured by the cosine similarity measurement as shown below.

$$sim(s_i, s_j) = \frac{\mathbf{p}_{s_i}^T \cdot \mathbf{p}_{s_j}}{\|\mathbf{p}_{s_i}\| \times \|\mathbf{p}_{s_j}\|} \quad (3)$$

For the convenience of computation, we use a matrix form representation $P = (\mathbf{p}'_{s_1}; \mathbf{p}'_{s_2}; \dots; \mathbf{p}'_{s_{|S|}})$ to denote the interest of all students where $\mathbf{p}'_s = \mathbf{p}_s / \|\mathbf{p}_s\|$ means the normalization of \mathbf{p}_s . Then the similarity matrix Sim can be simply written as:

$$Sim = P^T \times P \quad (4)$$

where $Sim_{i,j}$ is the result of $sim(s_i, s_j)$.

Based on the similarity, we could estimate the user-based interest score. For a student s and a course c , the Interest Score denoted as $IS(s, c)$, is defined as (5), where $S_{s,k}$ indicates the set of top- k similar students of s as neighbors, and $I_{C_{s'}}$ is an indicator function whose value is 1 when $c \in C_{s'}$.

$$IS(s, c) = \frac{\sum_{s' \in S_{s,k}} I_{C_{s'}} \times sim(s, s')}{\sum_{s' \in S_{s,k}} sim(s, s')} \quad (5)$$

Furthermore, we try to utilize students' major information together with their similarity as equation (6).

$$sim_m(s, s') = \lambda sim(s, s') + (1 - \lambda) samemajor(s, s') \quad (6)$$

Where $samemajor(s, s')$ function equal to 1 if student s and student s' have the same major, otherwise, the function equal to 0. λ (limited from 0 to 1) is used to control the weight between similarity and major information. The underlying rationale is that each major has its owner preference on courses enrolling, students have the same major will generally make a similar choice in course selection. Also, students in the same major are more likely to be friends or classmates, which brings potential social link information into the course recommendation. Then equation (5) can be rewritten as below.

$$IS(s, c) = \frac{\sum_{s' \in S_{s,k}} I_{c,s'} \times sim_m(s, s')}{\sum_{s' \in S_{s,k}} sim_m(s, s')} \quad (7)$$

3.2.2 Timing and popularity based Score

Different courses may have different suitable time periods (semesters). For example, in each department, courses can be taken by students of different grades, e.g., freshman or sophomore. Previous studies showed that the timing of courses has a strong correlation with student graduation GPA and time to degree [23]. Based on that, we assume that the timing of courses is also important for course selection. The suitable timing of courses will help students for good grades and successful graduation in a timely manner.

For each course c , we define the *Timing based Scores (TS)*, denoted as $TS(c, t)$, where t indicates a specific semester. In our framework, TS is considered from two aspects:

(1) Which semester is more suitable for taking this course? For a specific course, we sum up the number of enrollments for every semester and normalize all of the values. The result is denoted as $T_t(c, t)$.

$$T_t(c, t) = \frac{Num(c, t)}{Max_{t' \in T}(Num(c, t'))} \quad (8)$$

where $Num(c, t)$ represents the number of enrollments of course c in semester t , and T indicates the set of all time periods, i.e., 8 semesters for 4 academic years degree program.

(2) Which courses are popular now? For a specific semester, we sum up the number of enrollments for every course and normalize all of the values. The result is denoted as $T_p(c, t)$.

$$T_p(c, t) = \frac{Num(c, t)}{Max_{c' \in C}(Num(c', t))} \quad (9)$$

where C indicates the set of all courses. $T_t(c, t)$ and $T_p(c, t)$ are then fused by the harmonic mean since we want both of the two values are relatively high. The final *Timing based Score*, $TS(c, t)$ can be defined as:

$$TS(c, t) = 2 \times \frac{T_t(c, t) \times T_p(c, t)}{T_t(c, t) + T_p(c, t)} \quad (10)$$

Therefore, we can use $TS(c, t)$ to ensure that the semester t is suitable for taking the course c and the course c is suitable for taking in the semester t .

3.2.3 Grade-based Score

Improperly selecting courses would seriously affect the students' course achievements, which may decrease their GPA even enforce students to drop out. Accurately predicting students' grades in future courses has attracted much attention as it can help identify at-risk students early [30].

We use the grade prediction method called cross-user-domain collaborative filtering proposed by Ling et al. [12]. For predicting the score of each course $c \in C$ for each student $s \in S$, a small set

of senior students who have already enrolled on course c and have the most similar previous score distribution to student s will be discovered by means of Pearson correlation coefficient. The underlying rationale is that students with similar scores in the previous courses will generally obtain similar scores in the subsequent courses.

Let S_s denote the set of senior students who have already enrolled on course c . For any senior student $s_s \in S_s$, the following Pearson correlation coefficient is used to measure the course score similarity between student s and the senior student s_s .

$$sim(s, s_s) = \frac{\sum_{i \in C_{ss}} (g_{si} - \bar{g}_{si}) (g_{s_s i} - \bar{g}_{s_s i})}{\sqrt{\sum_{i \in C_{uu}} (g_{si} - \bar{g}_{si})^2} \sqrt{\sum_{i \in C_{ss}} (g_{s_s i} - \bar{g}_{s_s i})^2}} \quad (11)$$

where C_{ss} denotes the courses that are enrolled by both students s and s_s , $g_{s,i}$ and $g_{s_s,i}$ denote the grade of course i by students s and s_s respectively. \bar{g}_{si} and $\bar{g}_{s_s i}$ denote the average grade of courses enrolled by students s and s_s , respectively. Accordingly, the grade of the course c by student s can be predicted as follows.

$$g_{sc} = \frac{\sum_{s_s \in S_{s,k}} (g_{s_s c} - \bar{g}_{s_s c}) \times sim(s, s_s)}{\sum_{s_s \in S_{s,k}} sim(s, s_s)} \quad (12)$$

where $S_{s,k}$ indicates the set of top- k similar senior students of s . It should be noticed that students often achieve inconsistent grades in the various courses they take, and different students may have varying grades deviations, i.e. the grades deviation compared with the average grades among all students. Similarly, different courses may have varying grades deviations, i.e. the score deviation compared with the average score among all courses. In order to deal with those variations. We use the grade deviation of student s and the grade deviation of course c to predict student grades. Accordingly, equation (12) could be rewritten as below.

$$g_{sc} = b_{sc} + \frac{\sum_{s_s \in S_{s,k}} (g_{s_s c} - b_{s_s c}) \times sim(s, s_s)}{\sum_{s_s \in S_{s,k}} sim(s, s_s)} \quad (13)$$

where $b_{sc} = \mu + b_s + b_c$ denotes the baseline estimate for g_{sc} with μ being the overall mean grade of all courses enrolled by all students, $b_s = \bar{g}_s - \mu$ being the grade deviation of student s and $b_c = \bar{g}_c - \mu$ being the grade deviation of course c , where \bar{g}_s is the overall mean grade of student s and \bar{g}_c is the overall mean grade of course c .

Finally, we could use the grades that students are expected to obtain in future courses to boost the performance of our recommendation. The final *Grade based Scores*, $GS(s, c)$ can be defined as normalized values of grades.

$$GS(s, c) = \frac{g_{sc}}{Max_{c' \in C}(g_{s c'})} \quad (14)$$

The total score of student and course pair *score* (s, c) can be written as:

$$Score = \alpha \times IS(s, c) + \beta \times TS(s, t) + \gamma \times GS(s, c) \quad (15)$$

Where α, β, γ are parameters to control the proportion of weights from different sources. By taking those scores into account simultaneously, a course that the student interested in, and suitable for him to take to get a high grade could be ranked higher than other courses. Also, student could control the weighting of those components to have a better understanding of the data and decision-making.

3.3 Course Recommendation Algorithm

The whole framework can be written as Algorithm 1. Student set S , course set C , enrollment set $E(s, c, g, t)$ are input and output is a list of recommendations R_s for student's next semester that includes up to k recommendations per student.

Algorithm 1: Generating a list of course recommendations for student

Input :

Student set S , course set C , enrollment set $E(s, c, g, t)$;

Output :

Recommendation results for each student R_s .

- 1 Calculate student interest p_s for each $s \in S$ by equation 1;
 - 2 Calculate student interest similarity by equation 4;
 - 3 Calculate student grade similarity by equation 11;
 - 4 Calculate student deviation of each student;
 - 5 Calculate course grade deviation of each course;
 - 6 **foreach** $s \in S$ **do**
 - 7 Calculate user interest-based score $IS(s, c)$ by equation 7;
 - 8 Calculate timing-based score $TS(c, t)$ by equation 10;
 - 9 Calculate user grade-based score $GS(s, c)$ by equation 13 and equation 14;
 - 10 Calculate final score $Score(s, c, t)$ by equation 15;
 - 11 Let R_s be the sorted list of C ordered by its $Score(s, c, t)$ in descending order.
 - 12 **endfor**
-

4. EVALUATION

In this section, we conducted a series of experiments to evaluate the effectiveness of our proposed method. We first describe the dataset and experimental settings. Next, the evaluation methodology and metrics are introduced in detail. Finally, the results are shown in Section 4.4.

4.1 Dataset

This work focuses on undergraduate students in a traditional educational institution. We used a dataset from our university that spans for 5 years. The dataset consisted of per-semester course enrollment information of 2,366 students from 12 departments, with a total of 38,968 pseudonymized enrollment records from 2014 through 2018. Each row of the course enrollment data contained semester and department information, an anonymous student ID and course information included course name, instructor and course category.

4.2 Experiment Settings

4.2.1 Data selection

The most natural approach to evaluate the model is to split the data by semesters. As shown in Figure 1(b), most of the undergraduate students may take courses in the first two years. Therefore, for students who enrolled in 2015, the semester of Spring 2015 was used for training, the subsequent semesters of Fall 2015, Spring 2016 and Fall 2016 are regarded as the testing semesters, each of which is tested separately. The results are evaluated by comparing the predicted courses and the ground-truth courses he/she has enrolled in.

4.2.2 Comparison

We name our methods as Hybrid Course Recommendation (HCR). We compare our method with two group popularity approaches [14] and Random recommendation (Random). The two group popularity approaches including the department level (Grp-Pop-1), which recommend the most popular courses in the major, and the academic level (Grp-Pop-2), which recommend the most popular courses on the major and the academic level of the student ("freshmen", "sophomores", "juniors", and "seniors").

4.3 Evaluation Metrics

Like previous work [11,14,15,20], we used Recall@ns and Coverage as the evaluation metric for the performance.

Coverage is measured based on the percentage of courses that have been recommended at least once to students, which describes the ability of a recommendation system to explore the long-tail item.

Recall@ns is the percentage of actually enrolled courses of s in semester t that were contained in the recommendation list, where ns is the number of courses that the student took in the target semester. The reported metrics are averaged out across all students. Since our proposed course recommendation method considers both student interest and the grade he/she may obtain, we cannot only use the Recall metric, and instead, we use a variation of it. For the list of the courses R_s that recommended to a student s , Let T_s is the set of courses in the test set of s , A_s is the set of courses which student is expected to get the grade equal to or higher than his/her average previous grade. We use the ratio of $|R_s \cap T_s \cap A_s|$ and $|T_s \cap A_s|$ to measures the fraction of the actual well performed courses that are retrieved.

4.4 Results

4.4.1 Interest-based Score

In collaborative filtering strategy, taking how many similar students as neighbors is an important problem which is sensitive to the quality of the result. We investigate the performance of our interest model with different neighbor numbers. As shown in Figure 4, the performance of the model increases with the increase of neighbor number at first then decreases. According to the observation above, we pick a practical value 40 as the value of the neighbor number parameter in our follow-up experiments.

We also investigate the performance of our interest model with different weights between similarity and major information. As shown in Figure 5, we can observe that the performance of the model increases with the decrease of λ in terms of Recall. The reason is that the model considers not only the similarity but also the major information. That is, each major has its own preference for courses enrolling, major information will improve the performance of the algorithm.

However, 100% recall could be bad because the system just recommends what students do anyway. We noticed that the Coverage also decreases with the decrease of λ . The model seems benefit from the major information while scarifying the diversity of results. Recommendations for courses at other departments sometimes are useful to mine more long-tail student interest while students usually ignored that these courses existed or that their content matched their interests. To achieve the best performance of recommendation, we need to make a trade-off. According to the observation above, we set λ as 0.2 in our follow-up experiments.

Figure 4. Performance of different neighbor numbers.

Figure 5. Evaluation of major information.

4.4.2 Influence of different factors

To illustrate the influence of different factors, we set each parameter α, β, γ from 0 to 1 with a step size 0.05 to find the optimal combination.

Table 2. Performance of different parameters

Model	$(\alpha, \beta, \gamma) = (1, 0, 0)$	$(\alpha, \beta, \gamma) = (0, 1, 0)$	$(\alpha, \beta, \gamma) = (0, 0, 1)$	$(\alpha, \beta, \gamma)^*$
Recall@ns	0.380	0.412	0.341	0.434
Recall(a)@ns	0.311	0.315	0.332	0.322
Coverage	0.534	0.212	0.356	0.516

As shown in Table 2, the interest score and timing score has a good explanatory value for the recommendation than others. Also, the suitable timing of taking a course will help students to get a good grade. A recommendation only based on the grade has a good performance for recommending high grade courses. However, the results cannot help all the students. We reached the best Recall@ns with $(\alpha = 0.4, \beta = 0.45 \text{ and } \gamma = 0.15)^*$.

The results indicate that recommendations that are aimed only at one factor are likely not to be satisfied by every student. As we discussed before, different students may have completely different orientations based on their own reasons, which serves as different criteria such as their preferences, interests, needs, performance, etc. Such a hybrid system could provide explanations and user

controls for different categories of target students to support the interpretation of the data and decision-making.

Table 3. Evaluation of course recommendation

Semester	Model	Recall@ns	Recall(a)@ns	Coverage
Fall 2015	Random	0.048	0.036	-
Fall 2015	Grp-Pop-1	0.374	0.306	0.272
Fall 2015	Grp-Pop-2	0.452	0.342	0.342
Fall 2015	HCR	0.472	0.393	0.578
Spring 2016	Random	0.025	0.020	-
Spring 2016	Grp-Pop-1	0.325	0.201	0.305
Spring 2016	Grp-Pop-2	0.423	0.372	0.237
Spring 2016	HCR	0.431	0.402	0.342
Fall 2016	Random	0.002	0.002	-
Fall 2016	Grp-Pop-1	0.326	0.243	0.213
Fall 2016	Grp-Pop-2	0.441	0.387	0.250
Fall 2016	HCR	0.463	0.392	0.559

4.4.3 Comparison result

We analyze the performance of different algorithms. The results in Table 3 show that our framework performs well when compared with other methods.

As the results show, both of the Recall and Recall(a) of Random recommendation strategies are very low since there are a large number of courses, but each student only averagely chooses a few courses per semester. Hence, it is difficult to recommend the right course. Popularity approaches are having considerably satisfactory performance in Recall since popular courses which are taken by students frequently usually attract most of students. However, Grp-Pop-1 and Grp-Pop-2 do not consider student preference, it is also difficult to mine more long-tail student interest as the Coverage is low. In addition, Grp-Pop-1 and Grp-Pop-2 are not good in Recall(a) since they only consider the popular courses, ignore the performance the student is expected to get in the recommended courses.

5. CONCLUSION

This research aims to recommend suitable courses for learners and study how to design a personalized course recommendation in the university environments. In this paper, we propose a hybrid course recommendation framework that considers student interest, the timing and popularity of courses, and predicted performance of students, simultaneously. Experiments are conducted to confirm the effectiveness of the proposed approach. The results show that the proposed hybrid course recommendation approach performed well compared to other methods. Also, the model itself is flexible in the sense that one can easily adjust or extend it by changing the recommendation formula and incorporate more information.

ABSTRACT

Massive online Open Courses (MOOCs) make extensive use of videos. Students interact with them by pausing, seeking forward or backward, replaying segments, etc. We can reasonably assume that students have different patterns of video interactions, but it remains hard to compare student video interactions. Some methods were developed, such as Markov Chain and Edit Distance. However, these methods have caveats as we show with prototypical examples. This paper proposes a new methodology of comparing video sequences of interaction based both on time spent in each state and the succession of states by computing the distance between the transition matrices of the video interaction sequences. Results show the proposed methodology can better characterize video interaction in a task to discriminate which student is interacting with a video, or which video a student is interacting with.

Keywords

MOOC, Distance matrix, Edit Distance, Markov Chain, Optimal Matching Distance

1. INTRODUCTION

In online learning contexts, learner engagement is often measured by their interaction with video. The simplest measure is the total amount of time spent on video listening that can be used as an engagement measure [6]. But the availability of detailed interactions with a video allows more sophisticated measures, and comparison between video interactions.

Two common methods used to find the similarity between video interactions are the Markov Chain and Edit distance measures. The main limitation of using Markov Chain to compare video interactions sequences is that state transition probabilities do not take into account the time between states. Many sequences can have the same transitions probability matrix but represent different styles and length.

Boniface Mbouzaou, Michel Desmarais and Ian Shrier "Methodology to measure of similarity in student video sequence of interactions." In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 467 - 472

By contrast, the Edit distance approach to comparing video interaction sequences may take time into account if the sequences of events are mapped to a time scale and represented as activity segments, such as in [4]. However, large offset, such as a pause, in similar activity sequences will create large Edit distances that will shadow the similarity.

A methodology that can simultaneously take into account the time and transitions between activities could help the analysis of video interaction. It could help the analysis of the MOOCs and online teaching systems learning in video intensive environments, and could help to extract meaningful patterns of video interactions. It has often been used to classify students to identify students at risk (see for eg. [14, 8, 2]).

2. BACKGROUND

Among the different techniques to analyze video clickstream, some focus on extracting patterns, or motif, between events [3, 17, 16]. Descriptive statistics such as the video proportion played are also commonly used (see for eg. [15]). However, our focus is on measuring distance, or conversely similarity between video interaction patterns, and what are the most useful representations for that purpose.

We review the basics of the two families of methods and representations used in measuring video interaction similarity in more details and discuss their issues, before describing previous work with each approach, and then describe and evaluate the proposed method.

First, we describe the event data and a common transformation of events into activity sequences.

2.1 Events and activity sequences

Data on student interaction with videos relies on the notion of events associated to timestamps, such as "play" at 0:00:00 and "pause" at 0:00:10. There are five basic video interaction events: (1) *load*, (2) *play*, (3) *pause*, (4) *seek* and (5) *stop*.

The student can be considered in a state of listening to a video between 0 sec. and 10 sec., and in pause state thereafter. For example, suppose we have two students interactions:

Interaction sequences:

- 1: Play (4 seconds) then Pause (4 seconds) and then Play (4 seconds),

- 2: Pause (2 seconds) then Play (8 seconds) and then Pause (2 seconds).

Each student spent 12 seconds in total interaction with video. We can transform those two patterns of interaction into a sequence of activity states of 1 second intervals:

Activity sequences:

- 1: P1-P1-P1-P1-Pa-Pa-Pa-Pa-P1-P1-P1-P1
2: Pa-Pa-P1-P1-P1-P1-P1-P1-Pa-Pa-Pa
(P1=Play and Pa=Pause)

We will name this type of sequence an *activity sequence*, where a polling interval is defined and the activity corresponds to the last event that occurred. Activity sequence encoding has been used in a few studies of student interaction patterns with a learning system [4, 1].

We now turn to how these sequences can be represented.

2.2 Markov Chain representation

A Markov chain is specified by a set of states and transitions between states. The process starts in one of the state s_i , then moves to another s_{i+1} with a probability of $p_{i,i+1}$. The Markov property stipulates that the transition probability is independent of states prior to s_i .

Considering the video interaction events as states, a student interaction can be represented as a Markov state transition matrix, where cells contain frequencies of transitions in the sequence, normalized such that row sums are 1, and thus represent transition probabilities.

For example, the two *interaction sequences* in the section above would result in the following event sequences:

Event sequences:

- 1: P1-Pa-P1
2: Pa-P1-Pa

Contrary to *activity sequences*, *event sequences* do not carry the notion of a polling at regular time interval and ignore the time stamps on events. These event sequences would in turn result in a Markov Chain that is common to both:

$$\mathbf{M}_{\text{seq1.1}} = \mathbf{M}_{\text{seq2.1}} = \begin{matrix} & \begin{matrix} \text{play} & \text{pause} \end{matrix} \\ \begin{matrix} \text{play} \\ \text{pause} \end{matrix} & \begin{pmatrix} 0/1 & 1/1 \\ 1/1 & 0/1 \end{pmatrix} \end{matrix}$$

A measure of distance between sequences can be computed from the two Markov matrices, such as the Frobenius norm of the cell-wise difference between the matrices. More on this below.

The limit of using Markov Chain to compare video event sequences lies in the fact that transitions probabilities can be the same for very different sequences. This issue is evident in the two sequences above that end up having the same Markov transition matrix. While it can be alleviated by having a start end state, it is clear that the loss of state duration information will lead to a loss of valuable information.

However, Markov Chains are efficient at capturing transition patterns and have been used with some success for clustering [12, 11], for creating student profiles of interactions [10, 5], and for simulated students [7].

2.3 Sequence Edit Distance method

The sequence Edit Distance method relies on measures found with word distances, where alphabet similarity between words is the basis of calculating similarity.

Edit Distance (ED), generates distances that represent the minimal cost in terms of insertions, deletions and substitutions for transforming one sequence to another. The cost of each deletion, insertion or insertion is 1 by default. This algorithm was originally proposed by Levenshtein [9] and is most common when computing distances between words [13]. For video listening sequences, the principle is the same but the alphabet is represented by the activity. For example, the ED measure for activity sequences 1 and 2 above yields a distance of 9 over a maximum of 12.

A notable property of the ED measure is that sequences of different lengths will necessarily have a non null distance, and therefore potentially miss regularities in interaction patterns of different length sequences. On the contrary, a Markov Chain representation is not sensitive to sequence length, or to the number of transitions for that matter (since the row sums are all normalized to 1), whilst its capacity to capture interaction patterns in sequences of different length.

3. PROPOSED METHOD, TMED

The proposed method, named TMED, is a combination of the two techniques: the Markov Chain and the ED measure. The combination of results give a full similarity between each pair of student sequences of interactions benefiting of advantages from both techniques.

3.1 Transition matrix

The video transition matrix of a student s for a video is expressed as:

$$\mathbf{M}_s = \begin{matrix} & \begin{matrix} \text{load} & \text{play} & \text{pause} & \text{seek} & \text{stop} \end{matrix} \\ \begin{matrix} \text{load} \\ \text{play} \\ \text{pause} \\ \text{seek} \\ \text{stop} \end{matrix} & \begin{pmatrix} m_{1.1} & m_{1.2} & m_{1.3} & m_{1.4} & m_{1.5} \\ m_{2.1} & m_{2.2} & m_{2.3} & m_{2.4} & m_{2.5} \\ m_{3.1} & m_{3.2} & m_{3.3} & m_{3.4} & m_{3.5} \\ m_{4.1} & m_{4.2} & m_{4.3} & m_{4.4} & m_{4.5} \\ m_{5.1} & m_{5.2} & m_{5.3} & m_{5.4} & m_{5.5} \end{pmatrix} \end{matrix}$$

where $m_{j,k}$ is the *number of transitions* from event j to event k in an *activity sequence* obtained from an *interaction sequence*. And \mathbf{M}_s is the transition matrix of student s interacting with a video. Contrary to a Markov Chain, rows do not necessarily sum to 1. In the case where no event occurs and the student remains in the same state for awhile (playing video or pausing video, for eg.) the increase of the matrix element m_i is the maximum number of transitions possibles within the time spent in that state counting the transition from one state to the same state.

3.2 Distance between two transition matrices

The distance between two student transition matrix is expressed as:

$$\begin{aligned} d(\mathbf{M}_{s1}, \mathbf{M}_{s2}) &= \|\mathbf{M}_{s1} - \mathbf{M}_{s2}\|_F \\ &= \sqrt{\sum_{i=1}^5 \sum_{j=1}^5 (m_{s1,j} - m_{s2,j})^2} \end{aligned}$$

An important question is what is the polling interval to choose. This interval will determine the total number of transitions in M_s . The choice is determined by the minimal interval required to avoid skipping events while transforming the event sequence to the activity sequence. In our case, this interval is set to 3 per second and it applies to all video interactions. The total number of transitions, $T_{s,i}$ in a given interaction matrix \mathbf{M} for sequence s and video i is therefore:

$$T_{s,i} = L_{s,i} * N \quad (1)$$

where $L_{s,i}$ is the length of the interaction time and N is the polling interval.

The similarity between two interaction video sequences based on transition matrices with a video is then expressed as:

$$S_{mat}(\mathbf{M}_{s1}, \mathbf{M}_{s2}) = 1 - Dis(\mathbf{M}_{s1}, \mathbf{M}_{s2}) \quad (2)$$

$$Dis(\mathbf{M}_{s1}, \mathbf{M}_{s2}) = \frac{d(\mathbf{M}_{s1}, \mathbf{M}_{s2})}{T_{s1} + T_{s2}} \quad (3)$$

Where $S_{mat}(\mathbf{M}_{s1}, \mathbf{M}_{s2})$ is the similarity level between sequence of interaction of student $s1$ and student $s2$ of video i using matrix of interactions and $Dis(\mathbf{M}_{s1}, \mathbf{M}_{s2})$ is the dissimilarity between them. $d(\mathbf{M}_{s1}, \mathbf{M}_{s2})$ is the distance among them. T_{s1} and T_{s2} are the number of transitions of student $s1$ and student $s2$ sequence of the video i . If $S_{mat}(\mathbf{M}_{s1}, \mathbf{M}_{s2})$ is 0 then the two sequences are completely dissimilar and when it is 1 then they are completely similar. Between 0 and 1 shows the percentage of similarity between the two sequences of transitions.

3.3 Edit Distance measure (ED)

For each pair of sequences, we compute the ED distance to obtain the distance matrix and from there compute the level of similarity among them. The level of similarity between two sequences is computed using ED distance as:

$$S_{om}(seq_{s1}, seq_{s2}) = 1 - \frac{dist_{om}(seq_{s1}, seq_{s2})}{\max(T_{s1}, T_{s2})} \quad (4)$$

Where $S_{om}(seq_{s1}, seq_{s2})$ is the similarity level between sequence of student $s1$ and sequence of student $s2$ of video i and $dist_{om}(seq_{s1}, seq_{s2})$ is the ED distance between the two sequences and T_{s1} and T_{s2} are the numbers of transition of the sequence of each student given in equation (1). $\max(T_{s1}, T_{s2})$ is the maximum between the number of transitions of the two student sequences of interactions.

3.4 TMED

The last step of this proposed methodology is to combine the two techniques by taking for each pair of sequences the proper level of similarity among the levels given by each technique. This is meant to take into account the complementary of those techniques: one can find styles and give good similarity for sequences of different lengths and the other gives regularity among sequences and gives good similarity among sequences from the same range length. The final similarity level is then given by:

$$S(seq_{s1}, seq_{s2}) = Select(S_{om}(seq_{s1}, seq_{s2}), S_{mat}(\mathbf{M}_{s1}, \mathbf{M}_{s2})) \quad (5)$$

Where $S(seq_{s1}, seq_{s2})$ is the level of similarity between sequence of interaction $s1$ and $s2$, $S_{om}(seq_{s1}, seq_{s2})$ similarity

level between the two sequences based on ED distance as expressed in equation (4) and $S_{mat}(\mathbf{M}_{s1}, \mathbf{M}_{s2})$ similarity level between the two sequences based on sequence matrix as expressed in equation (2).

The function *Select()* selects S_{mat} similarity if one of the two sequences is less than the half-length of the other, and selects the maximum level of similarity between the proposed method and the ED method otherwise.

One takes the maximum between ED similarity and matrix similarity to avoid the ED drawback of finding dissimilarity between sequences of same range of length but some mismatch between states as illustrated in section 4 below. The flow of the proposed method is illustrated in Figure 1 from the sequences to the computation of their similarity level.

4. VALIDATION

To validate the proposed method, we compare its capacity of finding the level of similarity between sequences with existing methods, namely the Markov Chain technique as used by Klingler et al.[8] and the ED based method used for clustering the same kind of sequences of interactions.

4.1 Prototypical cases

We first test the approach over prototypical cases where the patterns are obvious to the eye. For this purpose we take two main cases: sequences of same lengths of transitions and sequences of different length of transitions. For the same sequence length interactions, we considered a cyclic same sequence of transitions as illustrated in Figure 2a. The cycle of transitions is: Lo-P1-Pa-P1-Pa-Se-P1-St. The cycle of transition can start anywhere and finish by *St* for any of the sequence.

The expected level of similarity should be close 100% as it is the same sequence following a cycle. The result based on ED distance cannot find that level of similarity as shown in Figure 2b compared to the Markov based method in Figure 2c (with some exceptions which do not reach the 100% similarity as expected, but close enough to be considered as such) and the proposed method in Figure 2d (finds perfect match of style by 100% similarity in each case). For these cyclic sequences, the proposed method and the Markov based similarity methods are performing better than ED based method in finding similarity between two cyclic same sequences of interactions.

The second validation of the proposed method is to compare it to a Markov based method for different length sequences given known similarities. For this purpose, we considered four sequences of same transitions levels as shown in Figure 3a. In this case, the percentage of transition between states is the same, but the time spent in each state is different from one sequence to another. The expected level of similarity depends here on the lengths of each sequence as the succession of states are the same for all four sequences. We should have then as result a progressive increase in level of similarity from the shortest sequence to the longest.

The result from the Markov Chain based method as in Figure 3a could not find the different levels of similarity as the percentage of transition between the states is preserved with

Figure 1: Flow of the proposed method to compute similarity between students' video sequences. "Select" is the selection process between the two technique similarity.

different sequences lengths. The proposed method performs better as shown in Figure 3b because it is based on the number of transitions rather than probability of transition as Markov Chain is.

4.2 Real dataset

The experiment on a real set of video interaction logs aims to test and compare the ability of the proposed method to recognize (1) the student behind an interaction log (data contains 4800 students), and (2) the video behind an interaction log. While this task is of no practical use, since both the video and student associated with an interaction log are already known in general, it provides a ground truth dataset to assess the discrimination power of each approach.

We choose three well-known classifiers such as support vector machine (SVM), boosted tree (GBM) and K-nearest neighbor (KNN) for each method of representation of sequence of interactions to predict first the student and then video to which sequence of interaction belongs. If a specific representation of student sequence of interaction is predictable in terms of which video and student that interact with the video, that means that the representation is able to better distinguish different types of interaction and even showing the specificity of a video in the way that students interact with it.

For the first part of the experiment where we predict student to which the sequence representation belongs, the algorithm arbitrarily selects one sequence of each student to predict among the nine (9) same student sequences representation and trains on the eight (8) others student sequences representation. The matrix distance used for Markov chain sequence representation and the proposed TMED representation is the one described above in section 2.2. In these two cases the dimension of the representation of each sequence is 25, that represent the 25 elements of transition matrix of each sequence representation as described in section 3.3. For the OM sequence representation, the matrix distance used is the one described in section ?? above. For the prediction 80% of the data is use for training and 20% for prediction. Each experiment is repeated 400 times using different set of students to predict (from 3 to 15 students). The data set is organized in such that all the student sequence present in the data set selected, the training set has 8 of their sequence representation and one in the testing set in each prediction run.

In the second part of the experiment, we used the same representations of student footage but instead of predicting the

student, we predicted the video the student interacted with. We used the same training (80% of the data) and test (20% of the data) sets, making sure that in the data we had the same number of students interacting with each video. Since each student has nine (9) sequences of interaction representation, the number of predicted classes (video 1 to video 9) in each data set considered is the same regardless of the number of students considered. For this reason, balanced precision was included in the results to avoid the effect of having more students. Again, in this case, at each prediction run, the algorithm ensures that each student sequence representation in the data set considered is the same as its sequence representations in the test set in each run.

4.3 Real data results

The results show that the proposed TMED method through the level of similarity. Through the tests of validation on prototypical data, the proposed method yields better results than the other two existing methods as one can see through Figures 2 and 3. For the same sequence represented as a cyclic sequence of interaction with various ways of representation show in Figure 2 (a) the expected degree of similarity 100% but only the proposed method give us the closest results to the expected one as shown in Figure 2. One can also see in this figure that the Markov chain based similarity is the second-best estimation of similarity after the proposed method based one.

When we consider a same sequence of states with different lengths of time as shown in Figure 2 (a), the expected results of similarity is a progressive increase of level of similarity according to the length of the sequence. The classic Markov chain based method could not find that the length of sequences are different whereas TMED method is able to find it well (Figure 3 (c)).

The experiment over the real data tasks tests the capacity of each method of representation of video interaction to identify each sequence of interaction in terms of student and video sequences. Results show better accuracy for TMED than the other ones (table 1). The performance parameters on student prediction using SVM, GBM and KNN on predicting five (5) students and twelve (12) students with nine (9) records of each student (where eight (8) records are for training and predicting one record of each student).

For predicting video, the complete results for forty-five (45) records from five (5) different students and hundred and eight (108) records from twelve (12) students in predicting the nine (9) videos are shown in table 2. They demonstrate

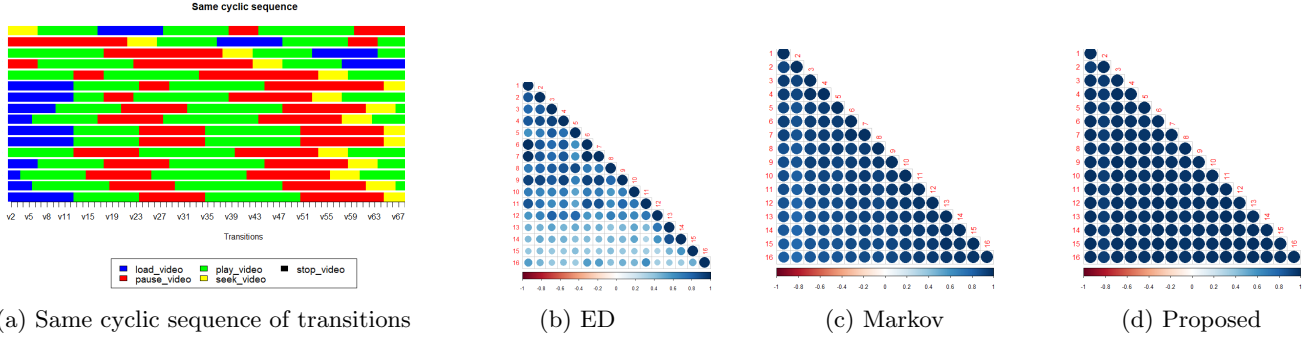

Figure 2: Result of similarity: (a) The cycle starts and follows the same pattern of transition to close the cycle (b) Similarity based on Edit Distance (ED) cannot recognize the similarity of cyclic sequences. (c) Similarity based on Markov Chain can recognize the similarity, with some exceptions that not reach 100%. (d) Proposed TMED similarity can recognize cyclic sequences.

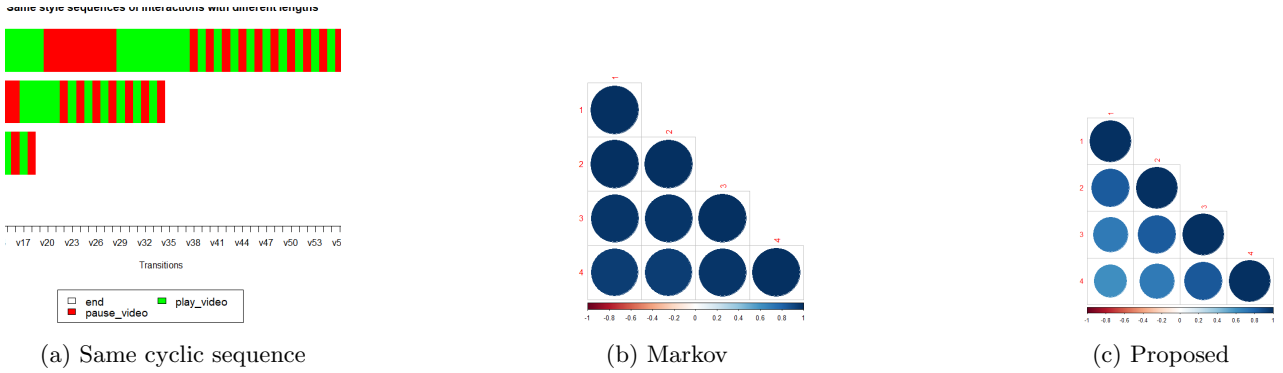

Figure 3: Similarity results from the sequence in (a): (b) similarity based on Markov Chain cannot recognize the duration in each state.(c) proposed TMED similarity can recognize the fact that those sequences are same but the level of similarity is based on the time spent in each state.

Predictions: 45 records, 5 target students									
Approach:	SVM			GBM			KNN		
Method:	ED	MC	TMED	ED	MC	TMED	ED	MC	TMED
Accuracy	0.60	0.00	0.80	0.40	0.00	1.00	0.20	0.22	1.00
F_1	0.75	0.00	0.89	0.57	0.00	1.00	0.33	0.36	1.00
Predictions: 108 records, 12 target students									
Accuracy	0.58	0.18	0.67	0.42	0.36	0.42	0.11	0.00	0.40
F_1	0.73	0.20	0.78	0.59	0.50	0.63	0.20	0.00	0.67

Table 1: Results of Twenty fold cross validation 400 runs of student prediction of 5 and 12 students using three different methods of representation of student interaction with videos showing that the proposed representation technique is performing better than others.

that the proposed method is also better on recognizing both video and student than the two other methods of presentation of student interaction with video.

These results suggest that the proposed method has a better way of representing a student video interaction with videos and so can be used for comparing two different interactions with video.

5. CONCLUSION

The proposed methodology aims to fill out a methodological gap on representing and comparing video sequences of interaction methods. The proposed method overcomes the drawbacks of the previous methods based on Markov Chain and sequence of interactions known as Edit Distance (ED). The main contribution of this proposed method is the fact that it takes into account the time spent in each state and the general style of succession of states. This offers a new tool to researchers who want to compared video viewers interaction and find eventually video style of interaction.

Predictions:		45 records, 9 target videos								
Approach:	Method:	SVM			GBM			KNN		
		ED	MC	TMED	ED	MC	TMED	ED	MC	TMED
Accuracy		0.11	0.33	0.56	0.33	0.56	0.56	0.22	0.22	0.33
F_1		0.20	0.50	0.72	0.50	0.36	0.72	0.36	0.36	0.50
Predictions:		108 records, 9 target videos								
Accuracy		0.22	0.11	0.56	0.11	0.33	0.56	0.22	0.11	0.22
F_1		0.36	0.20	0.61	0.20	0.50	0.61	0.36	0.20	0.36

Table 2: Results of Twenty fold cross validation 400 runs of video prediction using three different methods of representation of student interaction with videos, ED (Edit Distance), MC (Markov Chain), TMED.

TMED combines two styles of representation of video sequence of interaction and computes the similarity based on the advantage of each style of representation. The ED based similarity is generally good on same range length of interaction sequences and the matrix of interaction based representation does better on sequences of different range of length.

The proposed method is also able to better represent a sequence of interaction when doing classification tasks as the results show. In fact, proposed method has a better performance in predicting student sequence of interaction and prediction video when having a representation of a video sequence of interaction.

ABSTRACT

In colleges, programming is increasingly becoming a general education course of almost all STEM majors as well as some art majors, resulting in an emerging demand for scalable programming education. To support scalable education, teaching activities such as grading and feedback have to be automated. Recently, online judge systems have been extensively used for programming training, because they are able to automatically evaluate the correctness of programs in real time and thereby make grading work scalable. However, existing online judge systems lack of the ability to give effective feedback on logical programming errors. As such, instructors and teaching assistants are still overwhelmed by the work of helping students fix programs, especially for those novice students. To tackle the challenge, we develop **PIPE**, a deep learning model that is able to **Predict logical Programming Errors** in student programs. The model seamlessly integrates a representation learning model for obtaining the latent feature of a program and a multi-label classification model for predicting the error types in the program, thereby allowing end-to-end learning and prediction. We use the C programs submitted in our online judge system to train PIPE, and demonstrate its superior performance over the baseline models. We use PIPE to implement the error-feedback feature in our online judge system and enable automated feedback on logical programming errors to the students.

Dezhuang Miao, Yu Dong and Xuesong Lu "PIPE: Predicting Logical Programming Errors in Programming Exercises" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 473 - 479

The evolution of big data and AI technologies has made programming a ubiquitous skill in almost all industries and thereby led to a massive demand for programming professionals. In colleges and MOOC platforms, programming is no longer a professional course of ICT-related majors and becoming a general education course for all STEM majors and even some art majors. As such there is an urgent need for scalable programming teaching methodologies and learning tools to cater for the increasingly overwhelmed teaching workload. One of the most important mechanisms to achieve scalable teaching is automation. For example, online judge (OJ) systems [22], which are originally used for competitive programming contests, have now been extensively used in programming training mainly due to their ability of automated program evaluation. Given a programming exercise and a set of predefined input, the judge system evaluates a submitted program¹ by comparing the expected output with the actual output obtained from the execution of the program. Such a pair of predefined input and output is called a *test case*. This feature can largely reduce the grading workload of instructors and teaching assistants, and thus make class sizes scalable to some extent.

Despite the ability of automated program evaluation, existing OJ systems often provide to students next-to-zero feedback on programming errors when they submit an incorrect program. We refer to an "incorrect program" as a piece of code that is compilable but generates wrong output for the test cases. The errors in such a program are often termed as "logical errors", as opposed to "common errors" that are related to the use of incorrect syntax. In our teaching, we observe that the students can easily fix common errors with the help of an IDE, but are quite struggling when dealing with logical errors. In the latter case, existing OJ systems only show to students feedback such as "Wrong Answer" and "Runtime Error", and cannot provide any information on detailed types of errors. The problem is even severer in case of a quiz, where students are not allowed to check the test cases². As such, students, especially novices, rely heavily on instructors and teaching assistants to help them fix logical errors, which prevents programming training from becoming more scalable. This has motivated us to develop an automated tool for logical error feedback.

¹Below we use the term 'program' and 'code' interchangeably.

²Otherwise, students may fake the output.

In this work, we develop a deep learning model, PIPE, that is able to predict the detailed types of logical errors and therefore can be deployed in OJ systems to enable automated error feedback. We collect the C programs that are compilable but fail to pass the test cases, submitted by the students in our OJ system. We manually label the programs with a set of predefined types of logical errors. Since each program may contain multiple types of logical errors, we regard the prediction task as a multi-label classification problem. Therefore, the architecture of PIPE is inspired by the work of *code2vec* [2] and *C2AE* [24], which are originally developed to predict semantic properties of code snippets and boost the performance of multi-label classification tasks, respectively. In particular, we first use the idea of *code2vec* to obtain the latent representations of C programs. For each program, in addition to just embedding the code itself, we embed two more types of information in the model input, namely, the corresponding exercise identity and the evaluation results returned by the judge system. Then following the idea in *C2AE*, we also transform the corresponding error types into latent representations with an encoder, and jointly learn deep latent spaces together with the representations of the C programs. The error types are finally reconstructed from the deep latent spaces using a decoder, which are then used to compute the loss function with the true error labels for backpropagation. Thanks to the seamless integration of *code2vec* and *C2AE*, PIPE allows end-to-end training and prediction. We then conduct extensive experiments to demonstrate PIPE's superior performance over the baseline models. We deploy PIPE in our OJ system and show the usage of the automated error-feedback feature.

The rest of the paper is organized as follows. Section 2 presents the detailed architecture of PIPE. Then Section 3 describes the real dataset used in our experiments and presents the performance evaluation of the proposed model. Section 4 gives a brief literature review of related work, and finally Section 5 concludes the work and points out some future work to improve the feature of automated error feedback.

2. THE PIPE MODEL

We describe the architecture and the optimization method of PIPE in this section.

2.1 Architecture Overview of PIPE

Since each program may contain more than one logical error, we regard the error prediction task as a multi-label classification problem. We use the structure of the *C2AE* model as the backbone of PIPE. The *C2AE* model performs joint input and output embedding which correlates the features and the labels, and hence achieves the new state-of-the-art performance on multi-label classification tasks. In particular, PIPE uses a feature mapping \mathbf{F}_x to transform the programs \mathbf{X} and uses an encoding function \mathbf{F}_e to transform the corresponding labels \mathbf{Y} of the logical errors into deep latent spaces \mathbf{L} . Then it utilizes Deep Canonical Correlation Analysis [3] (DCCA) to learn \mathbf{L} for joint program and label embedding. Finally, PIPE uses a decoding function \mathbf{F}_d to recover the label outputs from \mathbf{L} , where \mathbf{F}_e and \mathbf{F}_d thus compose an autoencoder for the reconstruction of the labels. The objective function of PIPE is formulated as follows:

$$\Theta = \min_{\mathbf{F}_x, \mathbf{F}_e, \mathbf{F}_d} \Phi(\mathbf{F}_x, \mathbf{F}_e) + \alpha \Gamma(\mathbf{F}_e, \mathbf{F}_d) \quad (1)$$

where Θ represents the total loss of PIPE, $\Phi(\mathbf{F}_x, \mathbf{F}_e)$ and $\Gamma(\mathbf{F}_e, \mathbf{F}_d)$ denote the loss at the latent space layer for associating features and labels, and the loss at the output layer for reconstructing the labels, respectively. The hyperparameter α balances the two components of the objective function. Once the training is completed, PIPE can throw away the component pertaining to \mathbf{F}_e and use $\mathbf{F}_d(\mathbf{F}_x)$ to predict the logical errors in each program.

In PIPE, we simply use a fully-connected network to implement the functions \mathbf{F}_e and \mathbf{F}_d , respectively. We further leverage the idea in *code2vec* to implement the feature mapping \mathbf{F}_x for program representation learning, as shown in the part surrounded by the red dotted line in Figure 1. Rather than directly embed the source code, *code2vec* first decomposes the program into a collection of paths in its abstract syntax tree (AST) and then learns to aggregate the paths into a single program vector. The method is proved to better capture the regularities that reflect common program patterns and lower the learning effort, compared to learning over original program text. To capture more information about the logical errors pertaining to each particular exercise, we embed the exercise identity and the evaluation results on the test cases returned by the judge system, and concatenate them with the program vector to form a unified feature vector, which we call *program embedding*. Then the program embeddings are transformed into the latent space \mathbf{L} using a fully-connected layer. The architecture overview of PIPE is shown in Figure 1.

2.2 Program Embedding

Firstly, we need to transform the programs into vectorized representations. Following the method in previous work [2, 19], we compile each C program X and parse it to construct an AST. An AST is a tree representation of the abstract syntactic structure of source code, where the nodes denote the various elements appearing in the original source code. By traversing between the AST leaves, we can obtain multiple syntactic paths that represent the context of the corresponding C program. Then the syntactic paths are converted into context vectors, which are used as one type of input to learn the values of program embedding. Each context vector $\mathbf{c}_i \in \mathbb{R}^{3d}$ is concatenated to using three individual vectors, as depicted in Equation 2,

$$\mathbf{c}_i = [\mathbf{s}_i, \mathbf{p}_i, \mathbf{t}_i] \quad (2)$$

where $\mathbf{s}_i \in \mathbb{R}^d$, $\mathbf{p}_i \in \mathbb{R}^d$ and $\mathbf{t}_i \in \mathbb{R}^d$ are the vectorized representation of the source node, the path and the target node of the corresponding syntactic path, respectively. Then each context vector $\mathbf{c}_i \in \mathbb{R}^{3d}$ is transformed into a combined context vector $\hat{\mathbf{c}}_i \in \mathbb{R}^d$ using a shared fully-connected layer, and finally all the combined context vectors are aggregated into a single program vector $\mathbf{v}_p \in \mathbb{R}^d$ using the following attention mechanism,

$$\mathbf{v}_p = \sum_{i=1}^n \alpha_i \cdot \hat{\mathbf{c}}_i \quad (3)$$

$$s.t. \quad \alpha_i = \frac{\exp(\hat{\mathbf{c}}_i^T \cdot \mathbf{a})}{\sum_{j=1}^n \exp(\hat{\mathbf{c}}_j^T \cdot \mathbf{a})}$$

where \mathbf{a} is the attention vector, α_i is the attention weight and n is the number of combined context vectors. The attention vector learns the importance of each combined context

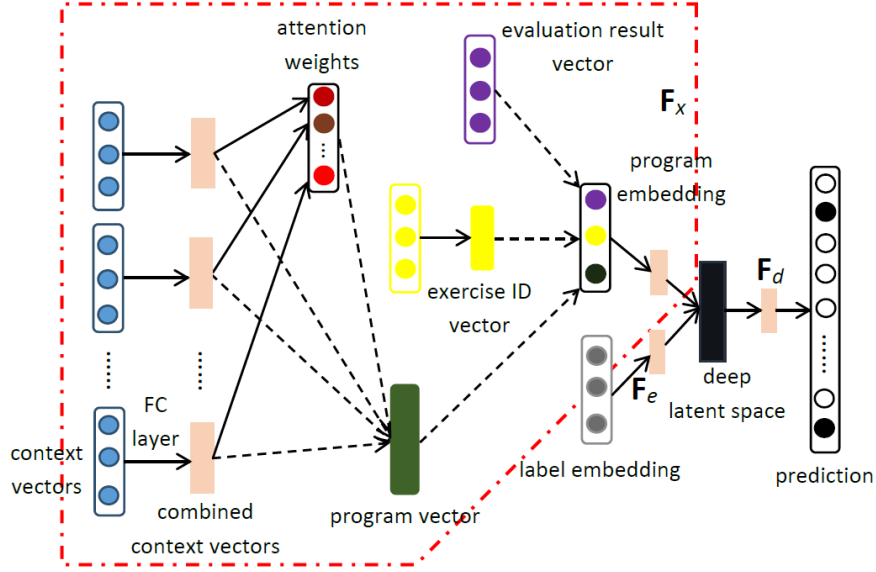

Figure 1: The overview of PIPE's architecture.

vector. To capture more information pertaining to the errors in the program w.r.t a particular exercise, we further embed the exercise identity and the evaluation results on the test cases into two vectors $\mathbf{v}_e \in \mathbb{R}^{d_e}$ and $\mathbf{v}_r \in \{0, 1\}^{d_r}$, respectively. \mathbf{v}_r is a bit vector where 1 indicates a correct output on the test case and 0 otherwise. The vector \mathbf{v}_e restricts the exercise-related characteristics such as functions and algorithmic logic, and the vector \mathbf{v}_r captures specific types of errors since similar logical errors should result in wrong output on similar test cases. Eventually the program embedding \mathbf{v}_x is obtained by concatenating \mathbf{v}_p , \mathbf{v}_e and \mathbf{v}_r , as formulated in Equation 4.

$$\mathbf{v}_x = [\mathbf{v}_p, \mathbf{v}_e, \mathbf{v}_r] \quad (4)$$

2.3 Learning Deep Latent Spaces for Joint Program & Label Embedding

Following the idea in the work [24], we learn deep latent spaces \mathbf{L} to associate program embedding and label embedding, using Deep Canonical Correlation Analysis [7, 3] (DCCA). For each C program X , we simply represent its label Y as a bit vector $\mathbf{v}_Y \in \{0, 1\}^N$, where N is the number of logical error types. The vector \mathbf{v}_Y may contain multiple 1s since each program may have multiple types of logical errors. Then both the program embedding \mathbf{v}_x and the label embedding \mathbf{v}_Y are transformed into a latent vector of size l using a fully-connected layer with the tanh activation function. The holistic functions that mapping X and Y are refer to as \mathbf{F}_x and \mathbf{F}_e , respectively, as depicted in Section 2.1. Then the objective function for correlating the latent representations are formulated as Equation 5,

$$\begin{aligned} \Phi(\mathbf{F}_x, \mathbf{F}_e) &= \|\mathbf{F}_x(\mathbf{X}) - \mathbf{F}_e(\mathbf{Y})\|_F^2 \\ \text{s.t. } \mathbf{F}_x(\mathbf{X})\mathbf{F}_x(\mathbf{X})^T &= \mathbf{F}_e(\mathbf{Y})\mathbf{F}_e(\mathbf{Y})^T = \mathbf{I}, \end{aligned} \quad (5)$$

where $\mathbf{I} \in \mathbb{R}^{l \times l}$ is the identity matrix. By solving the objective function, we enforce the deep latent space \mathbf{L} to associate the programs \mathbf{X} and the labels \mathbf{Y} , and hence $\mathbf{F}_x(X)$ can be used as the input to predicting the label Y .

2.4 Recovering Label Outputs from the Deep Latent Space

In the training phase, the output label \hat{Y} is reconstructed from the latent representation $\mathbf{F}_e(Y)$ using a decoder \mathbf{F}_d , which is simply implemented as a fully-connected layer in this work. In the original work [24], the model uses a label-correlation aware function to calculate the label reconstruction loss $\Gamma(\mathbf{F}_e, \mathbf{F}_d)$ at the output layer, in order to better preserve the label co-occurrence information for multi-label classification task. However, we notice that there is no strong correlation between the labels of the logical error types in our dataset. Hence, we instead use the multi-label cross-entropy function to calculate the label reconstruction loss, as depicted in Equation 6,

$$\begin{aligned} \Gamma(\mathbf{F}_e, \mathbf{F}_d) &= \frac{1}{|\mathbf{Y}|} \sum_{j=1}^{|\mathbf{Y}|} E_j \\ E_j &= - \sum_{i=1}^N y_i \log(\hat{y}_i) + (1 - y_i) \log(1 - \hat{y}_i) \end{aligned} \quad (6)$$

where $|\mathbf{Y}|$ is the number of training instances, N is the number of logical error types and y_i equals to 1 if the program contains the corresponding error and equals to 0 otherwise. We use the Sigmoid activation function in the output layer. By solving the loss function, we enforce the autoencoder $\mathbf{F}_d(\mathbf{F}_e(Y))$ to reconstruct the label of the logical error types. Since the latent representation $\mathbf{F}_e(Y)$ and $\mathbf{F}_x(X)$ are highly correlated after the training is completed, $\mathbf{F}_d(\mathbf{F}_x(X))$ can be used to predict the error types of a given C program X .

2.5 Optimization

The gradient of the label-reconstruction loss $\Gamma(\mathbf{F}_e, \mathbf{F}_d)$ can be easily calculated since it is a cross-entropy function. Following the method in [24], the gradient of the association aware loss $\Phi(\mathbf{F}_x, \mathbf{F}_e)$ in the latent space can be calculated with the help of Lagrange multipliers [20]. In particular,

$\Phi(\mathbf{F}_x, \mathbf{F}_e)$ is first reformulated as

$$\Phi(\mathbf{F}_x, \mathbf{F}_e) = \text{Tr}(\mathbf{C}_1^T \mathbf{C}_1) + \lambda \text{Tr}(\mathbf{C}_2^T \mathbf{C}_2 + \mathbf{C}_3^T \mathbf{C}_3), \quad (7)$$

where

$$\begin{aligned} \mathbf{C}_1 &= \mathbf{F}_x(\mathbf{X}) - \mathbf{F}_e(\mathbf{Y}) \\ \mathbf{C}_2 &= \mathbf{F}_x(\mathbf{X})\mathbf{F}_x(\mathbf{X})^T - \mathbf{I} \\ \mathbf{C}_3 &= \mathbf{F}_e(\mathbf{Y})\mathbf{F}_e(\mathbf{Y})^T - \mathbf{I}. \end{aligned}$$

We fix λ to 0.5 in accordance with [24]. Then the gradient w.r.t $\mathbf{F}_x(\mathbf{X})$ and $\mathbf{F}_e(\mathbf{Y})$ can be calculated as

$$\begin{aligned} \frac{\partial \Phi(\mathbf{F}_x, \mathbf{F}_e)}{\partial \mathbf{F}_x(\mathbf{X})} &= 2\mathbf{C}_1 + 4\lambda \mathbf{F}_x(\mathbf{X})\mathbf{C}_2 \\ \frac{\partial \Phi(\mathbf{F}_x, \mathbf{F}_e)}{\partial \mathbf{F}_e(\mathbf{Y})} &= 2\mathbf{C}_1 + 4\lambda \mathbf{F}_e(\mathbf{Y})\mathbf{C}_3. \end{aligned} \quad (8)$$

3. PERFORMANCE EVALUATION

In this section, we evaluate the performance of PIPE on a real dataset collected in our OJ system, and report the experimental results by comparing PIPE with other baseline methods. In the end, we demonstrate an example of the error-feedback feature implemented with PIPE in our OJ system.

3.1 The Dataset and Settings

The real dataset is collected from an introductory C programming course for undergraduate students in our school. The course uses heavily an OJ system to train the students, and we collect all the programs with logical errors submitted by the 29 enrolled students throughout one entire semester. Most programs have less than 50 lines. After cleaning work such as removing repeated submissions of programs with minor changes, we obtain 5196 C programs pertaining to 200 programming exercises. We have carefully designed for each exercise 10 test cases. Then we randomly disseminate the URLs of these programs to 17 senior students and ask them to annotate the labels of logical errors. In order to guarantee the correctness of annotation, they are allowed to freely run the programs and check the output of the test cases. Also, each program is annotated and cross validated by three students. The annotation work takes roughly two months.

After annotation, we observe that 5125 out of the 5196 programs fall into 10 major types of logical errors. The remaining 71 programs have very uncommon errors and are thus discarded from the dataset. The 10 types of logical errors are summarized and explained as follows. The distribution of the numbers of the errors is plotted in Figure 2.

1. **Incorrect input variables** - mainly due to misuse of the ‘&’ operator in the `scanf()` function.
2. **No output** - forgetting to write output.
3. **Incorrect output format** - output format not complying with the exercise requirements.
4. **Incorrect initialization** - errors related to incorrect initialization of variables.
5. **Incorrect data types** - mainly due to undesired type conversions.
6. **Incorrect data precision** - mainly due to loss of precision during calculation.

Figure 2: Distribution of the numbers of error types.

7. **Incorrect loops** - loop-related errors such as incorrect termination condition and incorrect step size of iteration.
8. **Incorrect branches** - errors due to incorrect conditional statements.
9. **Incorrect logic** - program’s logic not complying with the exercise.
10. **Incorrect operators** - misuse of operators.

The dataset is randomly splitted into training, validation and testing set with proportion 6 : 2 : 2 in the experiments. We implement PIPE and four baseline models for comparison using Python 3.6 and TensorFlow 1.13. The first three baseline models are the original code2vec model, code2vec plus exercise identity embedding, and code2vec plus exercise identity and evaluation result embeddings. The fourth model is the same as PIPE except that we use the original label-reconstruction loss in the C2AE model. At the input we randomly choose 200 context vectors for each program. At the output all the models are modified to cater for the multi-label classification task accordingly. The batch size is 64 and the learning rate is 0.001. We use the Adam algorithm for optimization. All other optimal hyperparameter settings are determined via the validation process, including the thresholds for rounding to the predicted labels. The metrics of interest are therefore precision, recall and F1 score, in accordance with [2, 24]. We also measure the averaged percentage of exact match, which means that the predicted types of errors are exactly the same as the ground truth for a given program. All experiments are conducted using a normal PC installed with an Intel Core i7-8550U CPU and 8GB RAM.

3.2 Main Results

The main results are presented in Table 1. For PIPE, the program embedding size is set to 138³, the size of the latent space is 69, and the balancing factor $\alpha = 0.1$. For each model, we calculate seven metrics on the testing set, which are the averaged percentage of exact match, per-class precision (C-P), per-class recall (C-R), macro F1 score (Ma-F1), overall precision (O-P), overall recall (O-R) and micro

³program embedding(138)=program vector(64)+exercise ID vector(64)+evaluation result vector(10).

Model	Exact Match	C-P	C-R	Ma-F1	O-P	O-R	Mi-F1
code2vec	0.5735	0.4037	0.3671	0.3822	0.7013	0.6472	0.6714
code2vec + exercise ID	0.5643	0.3696	0.3427	0.3543	0.6978	0.6437	0.6687

Table 1: Comparison between PIPE and baseline models.

F1 score (Mi-F1). We observe that PIPE performs constantly much better than the other models on all metrics. Although PIPE using original C2AE loss achieves the best overall recall, it has poor results on all other metrics. This is because the label-reconstruction loss in C2AE attempts to preserve the correlation between the labels and hence more error types are predicted. However, this also drastically reduces the precision and causes no case of exact match is predicted. The results prove the effectiveness of the seamless integration of code2vec and C2AE, as well as the use of cross-entropy for the label-reconstruction loss.

3.3 Sensitivity Analysis

We perform sensitivity analysis for three most important hyperparameters, that is, the size of program embedding v_X , the size of the latent space l and the loss balancing factor α . For each of them, we fix the values of all other hyperparameters and vary it in the corresponding ranges.

The size of program embedding. The size of v_X equals to the sum of the size of program vector v_p , the size of exercise identity vector v_e and the size of evaluation result vector v_r . The size of v_r is fixed to 10 since each exercise has 10 test cases, and the size of v_e is fixed to 64 for the sake of simplicity. We then vary the size of v_p in (64, 128, 192, 256), following the setting in [2]. Therefore, the size of v_X varies in (138, 202, 266, 330). The results are presented in Figure 3. We observe that PIPE prefers smaller program embedding size on all metrics.

The size of the latent space. Following [24], we measure the size of the latent space L as its ratio to the size of program embedding, i.e., $l/|v_X|$. We vary the ratio in the range [0.1, 1] with increments 0.1, and report the results in Figure 4. We observe that roughly all the metrics first increase and then decrease as the size of latent space increases. Overall taking half of the size of program embedding achieves the best performance.

The balancing factor α . We vary α in the range [0.1, 1] with increments 0.1. We also set $\alpha = 0.05$ to show the performance on the very small value. The results are presented in Figure 5. We observe that $\alpha = 0.1$ achieves the best overall performance. Further increasing α would break the balance between the losses of the two parts.

3.4 Demonstration

We have implemented the error-feedback feature in our OJ system using PIPE. Figure 6 shows the usage of the feature. In case of an incorrect submission, a student may check the possible errors predicted by the system and modify the program accordingly, where each type of error is associated with a probability. For example in Figure 6, the student may have

99.04% chance to write incorrect loops, and may also have 93.21% chance to lose precision during calculation, etc.

4. RELATED WORK

Code error prediction (or detection) is a branch of automatic software repair (ASR) [13], which is a long and active research area of software engineering. ASR is with respect to an oracle that is able to determine whether the execution of a given program is correct. Among various types of oracles, test suites or test cases are mostly used in recent ASR researches, which are also used as an important input feature in our PIPE model. Traditionally, test-suite-based methods can be broadly classified into two categories, i.e., search-based methodology [9, 8, 11] and semantics-based methodology [14, 5, 12]. The former category of methods explore a search space of programs to find the most suitable repair candidate that can pass the test cases; the latter category of methods synthesize a repair candidate using semantic information via symbolic execution and constraint solving. All these algorithms are specifically designed for repairing software with thousands to hundreds of thousands lines of code, and often cannot be directly applied in the setting of programming education. For instance, search-based methodologies typically rely on redundancy presented in other parts of the program to limit the search space, whereas redundant code is hardly observed in a students' program. Moreover, rather than directly correcting the bugs in students' programs, providing hints for students to find the errors is more preferable for education purpose. Therefore, the methods for ASR are somehow too heavy to cater for our prediction requirements.

In the past few years, research at the intersection of deep learning and programming languages has been driven by the availability of "big code". Massive source code obtained from the sites such as GitHub as well as some MOOC courses facilitates the design of learnable probabilistic models that exploit abundant patterns of code. These models are then applied to various applications, including program repair [1, 21], clone detection [10] and code synthesis [18], etc.

Training deep learning models to provide feedback to student code has recently drawn attention of both researchers and programming educators. For example, the work of [4] trains recurrent neural networks to automatically detect and correct syntax errors in programming assignments. The models are first trained on syntactically correct student programs and then are used to predict the correct token sequences given the prefix token sequence of a student program with syntax errors. Similarly, the work of [6] trains a multi-layered sequence-to-sequence neural network with attention to predict erroneous locations in student programs and attempts to fix the errors with correct statements. The

Figure 3: Varying the size of program embedding.

Figure 5: Varying the balancing factor α .

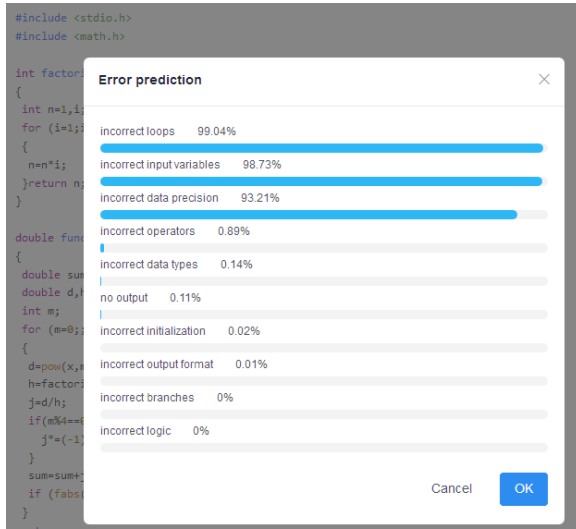

Figure 6: The usage of the error-feedback feature.

model requires to construct training pairs of syntactically incorrect program and the corresponding syntactically correct program. Since both works are focused on detecting and fixing syntax errors, they cannot generate abstract syntax trees for program embedding and thus directly use the language tokens in the original program text. The work in [16] trains an autoencoder to learn joint embedding of program states and programs. The embedding are then used as the input to train an RNN-based model, which can automatically propagate teacher feedback to similar programs. While the focus of their work is representation learning of program state, our model allows end-to-end learning and prediction of logical errors in programs. Other work pertaining to program feedback in the educational setting include [15, 17, 23].

5. CONCLUSIONS

To automate the feedback on logical programming errors in OJ systems, we develop PIPE, a deep learning model that is able to predict the types of errors in students' programs. PIPE seamlessly integrates program representation learning into a multi-label classification model, and thereby can perform end-to-end learning and prediction. To boost the prediction performance, PIPE also incorporates the exercise identity and the evaluation results on the test cases into the

program representation, with the hope that the error information w.r.t each particular exercise and each particular evaluation pattern could be captured. Experimental results on a real dataset show PIPE's superior performance over the baseline models. We have used PIPE to implement the error-feedback feature in our OJ system, and will further evaluate its impact on programming education.

In future, we plan to improve PIPE so that it may not only predict but also localize the errors, i.e., telling the students which lines of the program may contain logical errors and what are the potential types of the errors. Such feedback would further promote students' learning efficiency and help us to achieve higher scalability in programming education.

ABSTRACT

Assessing Opportunities to Learn (OTL) implies the measurement of different aspects of the curricular implementation in the classrooms, such as the contents that the teacher selects for the course and the time of exposure and the frequency of the tasks proposed.

Based on recent studies that demonstrate the influence of this curricular dimension on students' performance, this work analyzes the relationships between the emphasis made by teachers of third grade of secondary school on different reading contents, and students' performance in reading tests. The aim of this research is to establish the effect of the emphasis with which teachers propose different types of reading activities (literal, inferential, and critical) on students' performance. From the analysis of compositional data, this study concludes that the students of those teachers who report working a greater extent on the critical dimension of reading obtains –on average– higher scores on the national reading test. This result holds even when socio-economic and cultural context and reading habits are controlled for.

Keywords

Compositional data, curriculum emphasis, opportunity to learn, reading performance, regression models.

1. INTRODUCTION AND BACKGROUND

Leonardo Moreno, Matias Núñez, Cecilia Emery, Inés Méndez, Elisa Borba and Eliana Lucián "Incidence of teacher curricular emphasis in reading achievement of Uruguayan ninth-grade students" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 480 - 486

The opportunities to learn (OTL) that the education systems offer to students are currently one of the central objects of educational evaluations. This implies, among other things, the measurement of various aspects of the curricular implementation in the classrooms, such as: a) the contents that the teacher selects to address in the course and b) their exposure time and frequency according to the tasks proposed. As such, OTL studies have the potential to contribute to the knowledge of what and in which way the curriculum is implemented in the classroom, and to curricular formulations.

One of the first organizations to use the concept of OTL in their studies was the International Association for the Evaluation of Educational Achievement (IEA) in the Second International Study in Mathematics (SIMS), showing the correlation between student performance and the opportunity to have tackled a certain curricular content in class, see [30]. Likewise, the research produced from the SIMS data showed –among other aspects– the centrality of curricular coverage, emphasis, and time devoted to its treatment in relation to students results in tests, see [7].

The OTL project that served as a source for the design of the instruments used in the International Study of Trends in Mathematics and Science (TIMSS), was carried out by the Mathematics and Science Opportunities Survey (MSO) (see [32]), which formulates the concepts of prescribed curriculum (national goals or curricula), implemented curriculum and achieved curriculum (what students have actually learned, see [33]). In this sense, the evaluation of opportunities to learn proposes relevant information about the implemented curriculum that contributes to a better and more complete understanding of what students can learn.

Studies carried out by Cervini conclude that OTL affect stu-

dent performance even when controlling for variables such as socioeconomic status and socio-cultural context of the school: “students with the same social background who attend schools with a similar social composition, but some [have] a significantly higher performance level because their teachers gave them a greater opportunity to learn”, see [25].

Recently, and from the accumulation of evidence, greater importance has been given to the incidence of learning opportunities in student performances. Numerous studies realize the importance of considering these variables when identifying the aspects that influence student performance and that are also modifiable from the organization of schools and the pedagogical practices of the classroom, see [13].

Consequently, when evaluating the performance of students based on tests aligned to the prescribed curriculum (the regulations established to be taught in a school year) it is expected that different results will be observed for those who have had greater coverage of the contents or greater emphasis on its treatment, in addition to more exposure time to them (emphasis), than for those who have not had it, see [25]. The work that is developed in this article aims to give statistical evidence to this last hypothesis raised by Cervini in the Uruguayan classrooms.

On a large scale, there are few international experiences that evaluate learning opportunities in the classroom: the evaluations carried out by the IEA (SMSO and TIMSS), the International Study of Progress in Reading Comprehension (PIRLS), the Program for the International Assessment of Students (PISA) and the International Survey on Teaching and Learning (TALIS). Since 2017, the National Institute of Educational Evaluation (INEEd) of Uruguay, performs the national evaluation of achievements of the educational system (ARISTAS) that contemplates the measurement of OTL in classrooms of third and sixth grade of primary education and third grade of secondary education.

Research based on PISA data (see [17]) has shown, for a large group of countries, a significant association (of moderate to strong) between reading habits (students’ taste for reading, time dedicated to it in their free time and the diversity of texts they read) and their reading performance.

Similar findings were reported for Uruguay by ANEP, 2004. In this study, the relationship between certain attitudinal variables regarding students’ reading habits and the results of reading and math tests is analyzed. In concordance with international findings, this study shows better reading results for women than men. Nonetheless, it is also women who show greater taste for reading. Among the findings of this study, it is noted that as performance in reading improves, so does the taste for reading, while the dislike of it decreases on average.

Although there is evidence that links student reading habits with their reading performance. This can happen since student reading habits allow some teacher practices, that in turn influence student performance. However, there is little evidence that links these qualities of students with teacher practices (see [4]) and their performance. Thus, this research focuses on the relative effect of teaching practices on

the reading performance of students, when certain student qualities (such as socioeconomic and cultural level; and student reading habits) are controlled for.

Based on data from the 2018 national evaluation of the Uruguayan educational system –Aristas– carried out by the National Institute of Educational Evaluation (INEEd), the aim of this work (considering recent studies that demonstrate the influence of curricular implementation on student performance) is to analyze the relationships between the emphasis made by nine grade teachers on different reading dimensions (literal, inferential and critical) and their student performance on reading.

One possible explanation is that the students whose teachers report working the critical dimension of reading on a greater extent, achieve –on average– higher scores in the reading test, even when socio-economic and cultural context; and reading habits, are controlled for.

This paper is organized as follows. In Section 2 the theoretical framework and the main linguistic concepts used are introduced. Section 3 provides the implemented methodology and the statistical tools used: Compositional Data Analysis (CoDA). The most relevant results obtained from the statistical analysis are enumerated in Section 4. In Section 5 the final discussion and conclusions are established.

2. THEORY

As Zakaryan (see [35]) indicates, in general terms, the nature of classroom teaching significantly affects the level of student learning. In this relationship, the analysis of the teaching practice is key, since the teacher determines the learning opportunities through the activities he proposes in the classroom and the qualities of his or her teaching. Thus, the content, format and cognitive demand of the tasks that teachers pose in the classroom constitute “the main vehicle to provide school children with learning opportunities”, see [28], p. 113.

One of the questions which OTL studies attempt to respond is whether the curriculum implemented by teachers in the classrooms effectively covers the contents established in the nationally prescribed curriculum. Within this research perspective, three approaches are identified: the coverage of the contents, the exposure to them –measured through the time dedicated to them– and the emphasis on their implementation, that is, what contents are treated with priority in the classrooms over others in the program, see [26].

In this way, it is possible to approach the institutional and pedagogical mechanisms that contribute to the distribution of learning opportunities not only among schools, but also between classrooms. Likewise, it is relevant to know the form of said distribution, that is, if all children and young people receive from the school system –or not– the same opportunities to learn.

This work follows the definition of opportunities to learn (OTL) carried out by the INEEEd, see [15]. In this, the study of the OTL not only seeks to analyze the alignment between the prescribed and the implemented curriculum, but also to what extent this alignment and other school conditions in-

fluence the performance of the students. Among the dimensions of the OTL assessed by the INEE, this paper focuses on coverage and sequence of the contents, which refers to the degree of implementation of the curricular contents, as well as their didactic sequence and emphasis, see [15], p. 14. In particular, the emphasis on curricular content is measure as the percentage of classroom pedagogical time that teachers devote to the work of curricular content corresponding to a school grade, see [15], p. 15.

3. METHOD

This study uses data from the evaluation of the uruguayan education system (Aristas) carried out by the INEE in secondary education in 2018 nationwide. This evaluation gathers information on various actors of the education system: school principals, teachers and students, through self-administered online surveys. Aristas is applied to a representative sample of nine grade middle school students of the Uruguayan urban region. Besides this contextual questionnaires, each student has to take two multiple choice tests to assess reading and math performance (Students' abilities are estimated based on test results using item response theory, and in particular the Rash model).

To obtain information on curricular implementation, Aristas asks teachers if they have covered and with how much emphasis, a series of curricular activities that can be classified into three reading dimensions: literal, inferential and critical.

As defined by INEE in the OTL framework for secondary education (see [14] and [15]), the emphasis with which teachers work the curricular contents in the classroom is a composite measure based on their reports on: i) the total number of classes taught and ii) the number of classes dedicated to addressing each type of activity in the course. Both measures refer to the period between the beginning of the school year (March 2018) and the time the evaluation was carried out (October 2018).

In order to address this, teachers are presented with a list of 10 activities (corresponding to the three different dimensions of reading –literal, inferential, critical–) and are asked to indicate the number of classes dedicated to each activity. Each of the dimensions in which the activities are grouped implies differences in their cognitive complexity, see Table 1. Thus, the number of classes reported per dimension is counted as the average number of classes declared for each of the listed activities. That is, the number of classes reported by a teacher in one dimension is the sum of classes that the teacher declares to dictate for the activities that integrate that dimension, over the total of activities that compose it.

From the self-report declared by nine grade teachers in secondary education, an overestimation of the effective number of classes in the school year is generally observed. That is, when the maximum total number of classes in the year is 72%, 70.2% report dictating above that threshold. This inconvenience in the instrument is a frequent problem due to various causes, see [10] and [4].

To approach this over report problem, the classes reported are relativized by each teacher for the activities of each di-

	Literal dimension	Inferential dimension	Critical dimension
Kinds of activity	Recognize basic elements of the enunciation situation	Recognize the subject of the paragraph or statement	Evaluate and / or interpret the facts, situations or concepts posed by the text
	Locate explicit information	Summarize the general idea of the text and draw conclusions	Recognize items complexes of the enunciation situation (assumptions, implications, reasons, ideological position of the enunciator, intertextuality, parody, irony, exaggeration)
	Recognize the thematic progression	Recognize narrative, descriptive, argumentative or expository intentionality	
		Match information of sentences and paragraphs	
		Hierarchize data or events and establish relationships between texts when it has different formats (eg tables and text)	

Table 1: Activities classified according to the dimension they conform. Source: own elaboration.

mension of reading to the total of classes according to the school calendar. It is assumed that the relative weight that the teacher reports in each activity is a valid measure of the real time spent in class.

The classes reported by the i -th teacher to the literal, inferential and critical reading respectively are called L_i , I_i and C_i , so the normalized vector is

$$X_i = (LR_i, IR_i, CR_i) = \frac{1}{L_i + I_i + C_i} (L_i, I_i, C_i).$$

Let S^2 be the unit simplex of \mathbb{R}^3 ($S^2 = \{(x, y, z) \in \mathbb{R}^3 / x + y + z = 1, x \geq 0, y \geq 0, z \geq 0\}$). It is true that $X_i \in S^2 \forall i = 1, \dots, N$, where N is the total number of teachers in the sample ($N = 364$). In this way, conclusions can be drawn about the behavior in relative but not absolute terms. The isometric transformation is then given by $\phi: R_{\geq 0}^3 \rightarrow S^2$, where $\phi(x, y, z) = \left(\frac{x}{x+y+z}, \frac{y}{x+y+z}, \frac{z}{x+y+z} \right)$ y $R_{\geq 0}^3 = \{(x, y, z) \in \mathbb{R}^3 / x, y, z \geq 0\}$.

This means that the class proportions dictated (on average) in each of the three dimensions of reading (literal, inferential and critical) are thought of as compositional data. In this sense, the vector is made up of three components, each of which represents the proportion of classes dictated in that dimension, therefore the components of the vector of proportions are non-negative and add to 1. This vector indicates the relative emphasis the teacher reports assigning to each of the dimensions. This type of compositional data analysis doesn't allow for classical or hierarchical regression models as its assumptions don't hold.

The analysis of compositional data dates back to Pearson 1987, but the basis of statistical theory for this type of data has been developing since the middle of the last century, see [12], [8] and [9]. The association that exists between the components of the vector determines a series of methodological difficulties (see [34]) that lead to the need for specific techniques for this type of data.

A large number of applications of compositional data theory are found in the literature for different fields (see for example [5], [23], [20] and [27]). However, there are few applications in reference to educational data and in particular in the area

of educational evaluation, see for example [31], [19], [21] and [6].

On the other hand, reading achievement is assessed through a standardized reading test developed by INEEd. The test is designed based on a general statement of reading (reading competence) which is successively broken down into statements (dimensions of said competence: literal, inferential and critical) and subaffirmations (knowledge and skills). Test items are designed to assess students mastery of the subaffirmations. From a psychometric perspective, the Item Theory Response (TRI) method is used for the calibration and construction of the items. For the porpoise of this study, the group performance or ability (Y_i) is the average of the scores assigned by TRI to all the students of the i th-group.

4. RESULTS

Data from Aristas 2018 in Uruguay shows a relationship between socioeconomic level and reading habits of the group, and the emphasis the teacher assigns to certain reading activities over others, see [4]. Higher socioeconomic levels and more frequent reading habits of the group are associated with more teacher emphasis on the dimension of critical reading. Even when socioeconomic level is controlled for, the reading habits of the group have a significant effect over teacher emphasis.

Figure 1 shows, by means of box plot, the strong relationship between the quintiles of the socioeconomic level of the group (ESCS) and the average reading performance obtained by the group of students (left panel). Moreover, higher reading habits of the group also have an effect, (not as pronounced as ESCS) on student performance (right panel).

Figure 1: Left Panel: Box plot of the average performance of the group in the reading test according to the socioeconomic quintile of the group. Right Panel: Box plot of the average performance of the group in the reading test according to the level of reading habits of the group.

The relationship between reading test results and emphasis placed by teachers on each of the three dimensions of reading, is evaluated. As Figure 2 shows, groups who perform better on the test devote more time to activities that involve critical reading. Moreover, as group performance improve, the proportion of classes dedicated to literal reading decreases. These trends don't appear to apply to inferential reading.

However, these results are a) only descriptive of the sample and b) they are marginal, that is, the joint effect of the activity vector on student performance and its relative importance vis-a-vis other variables of the study (ESCS and

Figure 2: Box diagrams of the proportion in each of the activities (literal-inferential-critical) according to the quartiles of the group's performance variable.

reading habits) is not observed.

To model the problem, a non-parametric regression model (kernel method, see [18]) and a parametric regression model (Dirichlet regression, see [29] and [24]) are considered, see Figure 3. This figure reflects the average percentages of emphasis placed on each dimension as a function of the group's performance. On average, according to the non-parametric model, the emphasis on literal reading is among 20% and 35%, decreasing as Y increases. The influence of Y on the proportion of activities in critical reading varies between an average range of 27% to 50% increasing as Y increases. The inferential reading is the one with the least variation as a function of Y , between 30% and 38%.

In both cases it is observed that increasing group's performance is associated to an increase in the proportion of classes in which critical reading activities are taught.

Figure 3: Non-parametric regression by kernel method (points) and Dirichlet regression (continuous line) in S^2 where the independent variable is the performance of the group (Y).

This result holds for the Dirichlet model. In this case the decrease of literal reading emphasis is associated with higher test results but with a moderate statistical significance (p -value = 0.07), see Table 2.

Coef.	ANOVA

Y	0.46	0.07	8.94e-11

Table 2: ANOVA of the Dirichlet regression where the independent variable is the performance of the group (Y).

A possible mistake when interpreting these results is to infer a direct association between emphasis and student performance when, strictly speaking, it could be an indirect effect caused by student reading habits and socio-economic and cultural level of the group, see [4]. Figure 4 shows these interactions.

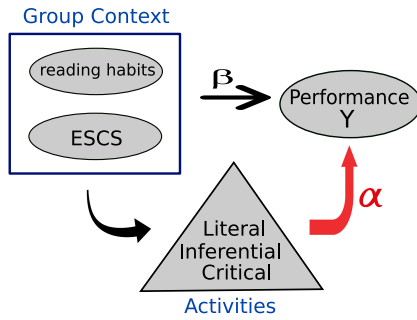

Figure 4: Diagram on the relationship between activities and performance controlling for ESCS context variables and study habits.

To control the effect of socioeconomic status and reading habits on performance, two step regression is estimated. The performance of the group in reading Y can be decomposed as the sum of a β (hypothetical or latent) score generated by certain context variables (in this model they are the *ESCS* and reading habits noted as H) and another α associated with the emphasis of classes in each activity, that is

$Y = \text{Intercept} + \beta + \alpha + \epsilon$, where ϵ is a random error centered and independent of α and β . In this case, student performance is considered as the dependent variable (as opposed as in Figure 3).

The strong relationship between β and Y has already been widely studied, see [14]. If the last term α is also significant to explain performance, this indicates that emphasis on a certain type of activities also influences performance, even controlling for certain group context variables. To “extract” the effect of the context, the following procedure is performed. As a first step, to avoid the ipstative effect (see [11]) between the components of the vector in S^2 an isometric transformation is carried out that goes from S^2 to \mathbb{R}^2 . This is called the log-ratio isometric transformation (*ilr*), see [1]. The image of (LR, IR, CR) is noted by (ilr_x, ilr_y) .

The first adjustment is then a linear model of the form,

$$Y = a_0 + a_1 ilr_x + a_2 ilr_y + b_1 ESCS + b_2 H + \epsilon \quad (\text{Model 1}).$$

Table 3 shows how all the variables are significant in this model, with the variables of S^2 tolerating the inclusion of H and *ESCS* in the model.

Coef.	ANOVA		
Model 1	Coef.	Error	p-value
Intercept	-0.11	0.025	4.06e-06
<i>ilr_x</i>	0.15	0.050	0.01820
<i>ilr_y</i>	0.12	0.042	0.00586
<i>ESCS</i>	0.68	0.04	< 2e-16
<i>H</i>	0.32	0.082	0.00013
Model 2	Coef.	Error r	p-value
Intercept	-0.10	0.026	< 3.44e-05
<i>ilr_x</i>	0.15	0.053	0.00465
<i>ilr_y</i>	0.14	0.044	0.00146

Table 3: ANOVA considering *ESCS* and *H* as control variables.

Second, after estimating the coefficients of the equation for maximum likelihood, the effect on the performance of the context variables is extracted, that is, $Y_i^* = Y_i - \hat{b}_1 ESCS_i + \hat{b}_2 Habitos_i$. The final model (model 2) that allows us to deduce the effect of emphasis on each dimension is,

$$Y^* = d_0 + d_1 ilr_x + d_2 ilr_y + \epsilon^* \quad (\text{Model 2}).$$

The ANOVA results of the Model 2 are also found in Table 3.

If the inverse *ilr* transformation is performed to the estimated coefficient vector of Model 2, the coefficient vector in S^2 is obtained, $(LIT, INF, CRIT) = (0.28, 0.35, 0.37)$ which allows to conclude that the emphasis on certain activities allows to obtain a better performance, still subtracting the effect of the context.

Figure 5 shows the level curves of the estimated regression function in Model 2. Even when controlling for the context variables, teachers who emphasize the activities of critical reading versus literal reading obtain –on average– a better group performance in the reading test. Higher intensities of gray indicate larger group performance.

It is important to highlight that Model 2 has high variability, which makes it possible to conjecture that other group, school or teacher variables that influence performance are not being accounted for in the model.

5. DISCUSSION AND CONCLUSIONS

This paper analyzes the relationship between the emphasis placed by teachers on different classroom reading activities (literal, inferential and critical reading), and the reading performance of their nine grade students in Uruguay. This makes it a novel contribution to educational policy in Uruguay as the topic has never been studied, and it is also a contribution to educational evaluation, as it applies the analysis of compositional data to this field of research.

Findings show a relationship between reading test scores and the emphasis placed by teachers on different reading

Figure 5: Level curves set of the estimated regression function in Model2.

dimensions. Better test results are associated with teacher emphasis on critical reading activities. Nonetheless, this relationship is not direct as it is affected by other variables such as the socioeconomic and cultural level of the group of students and their reading habits. However, even when controlling for these variables, the evidence holds: greater emphasis placed on critical reading activities versus literal reading is associated with higher group results on the reading test.

Moreover, findings also suggest the omission of certain variables that can be relevant to explain reading performance by students. It could be the case of prior reading achievement. Although it could be argued that teachers place more emphasis on critical reading activities when their students are better prepared for that (when they have higher prior reading achievement), evidence from primary school students from Uruguay shows that is not necessarily the case, see [16]. Nonetheless, this will be explored in future research.

In Uruguay, the differences in academic achievement are strongly related to socioeconomic factor, see [23], [2] and [3]. This study shows that having those factors controlled, the OTL offered to student variable is still relevant on achievement data. The dimension of this finding has implications not only on the teaching profession but also on public educational policies.

ABSTRACT

A challenge in digital learning games is assessing students' learning behaviors, which are often intertwined with game behaviors. How do we know whether students have learned enough or needed more practice at the end of their game play? To answer this question, we performed post hoc analyses on a prior study of the game *Decimal Point*, which teaches decimal numbers and decimal operations to middle school students. Using Bayesian Knowledge Tracing, we found that students had the most difficulty with mastering the number line and sorting skills, but also tended to over-practice the skills they had previously mastered. In addition, using students' survey responses and in-game measurements, we identified the best feature sets to predict test scores and self-reported enjoyment. Analyzing these features and their connections with learning outcomes and enjoyment yielded useful insights into areas of improvement for the game. We conclude by highlighting the need for combining traditional test measures with rigorous learning analytics to critically evaluate the effectiveness of learning games.

Keywords

Decimal, Digital Learning Game, Bayesian Knowledge Tracing, Over-practice

1. INTRODUCTION

Digital learning games are typically regarded as a powerful tool to promote learning by engaging students with a novel and interactive game environment. While there have been concerns about the lack of empirical results on learning games' effectiveness [21, 32], recently we have seen more research that addresses this issue by showing students' learning gains from pretest to posttest in rigorous randomized experiments [9, 41, 52]. More generally, a meta-analysis of 69

studies by [10] showed that game conditions promoted significantly more learning than non-game conditions with equivalent knowledge content, and that augmented game designs with more learning-oriented features were more instructionally effective than standard designs.

While this prior research has demonstrated that digital learning games can enhance learning, the next step is to examine how they do so. In particular, even though the common measures of pretest and posttest scores are necessary to evaluate students' transferable learning, they are inadequate to address many questions about how learning takes place during the game. For example, did students get just enough practice from the game, or more practice than necessary? How does in-game learning correlate with test performance? These questions have been explored in great detail in Intelligent Tutoring Systems (ITS), but not as much in digital learning games, primarily because of the differences in design approaches between these two platforms. ITS are typically very structured environments where students are frequently evaluated on their knowledge and, in the mastery learning settings [28], move to a new skill as soon as the system determines they have mastered the current skill. In contrast, digital learning games emphasize students' freedom in shaping their own learning experience without concern about the consequences of failure [15]; as a result, the game's learning objectives are not always obvious to the students [4]. The question, then, is how can we combine the traditional pretest and posttest measures in learning game studies with learning analytics methods from ITS to paint a better picture of students' learning, both inside and outside of the game context? Furthermore, given the game's dual goal of promoting both learning and enjoyment, do in-game learning metrics also relate to students' enjoyment in any meaningful way?

Our work explores these questions in the context of *Decimal Point*, a game that teaches decimal numbers and operations to middle-school students. Here we present a post hoc analysis of the data from a prior study [22]. First, we investigated how well students mastered the in-game skills, how long it took them to master each skill, and whether students continued practicing after mastery. Next, we used student data from before and during game play to predict their learning outcomes and enjoyment after the game. Based on this re-

Huy Nguyen, Xinying Hou, John Stamper and Bruce McLaren "Moving beyond Test Scores: Analyzing the Effectiveness of a Digital Learning Game through Learning Analytics" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 487 - 495

sult, we derived lessons for improving learning support in *Decimal Point* as well as in a more general learning game context.

2. RELATED WORK

2.1 Learning Analytics in Games

In-game formative assessment can be a powerful complementary tool for capturing students' learning progress [59]. Traditional formative measures typically make use of game-based metrics, such as the number of completed levels or the highest level beaten [2, 11], but these metrics may not always align with actual learning. Prior studies on *Decimal Point*, for instance, reported that students who played more mini-game rounds did not learn more than those who played fewer [18, 39]. An alternative approach is to employ learning analytics methods from ITS studies. For example, learning curve analysis, which visualizes students' error rates over time, has been applied in several learning games and yielded valuable insights that range from instructional redesign lessons to discovery of unforeseen strategy by students [17, 29, 42].

Learning analytics techniques can also connect formative assessment with external performance. For example, Bayesian networks have been applied to predict posttest responses from students' in-game data in several learning games [30, 48, 54]. Similarly, [27] employed feature engineering and gradient boosted random forest algorithm to identify struggling students in real-time in a physics learning game. Recently we have also seen more usage of deep learning for this prediction task [24, 51]. In general, research work in this direction can illustrate how well students' learning aligns with the game's learning objectives, while also guiding the development of adaptive support game features.

2.2 Decimal Point

Decimal Point is a web-based single-player digital learning game that helps middle-school students learn about decimal numbers and their operations (e.g., adding and comparing). The game features an amusement park metaphor, with a map of the park used to guide students (Figure 1). There are 8 theme areas with 24 mini-games, connected by a line that is designed to interleave skill types and theme areas. Each mini-game is aimed at helping students solve one of the common decimal misconceptions: **Megz** (longer decimals are larger), **Segz** (shorter decimals are larger), **Pegz** (the two sides of a decimal number are separate and independent) and **Negz** (decimals smaller than 1 are treated as negative numbers) [25]. Also, each mini-game calls for one of the following skills:

1. **Addition**: add two decimals by entering the carry digits and the sum.
2. **Bucket**: compare given decimals to a threshold number and place each decimal in a "less than" or "greater than" bucket.
3. **Number Line**: locate the position of a decimal number on the number line.
4. **Sequence**: fill in the next two numbers of a sequence of decimal numbers.
5. **Sorting**: sort a list of decimal numbers in ascending or descending order.

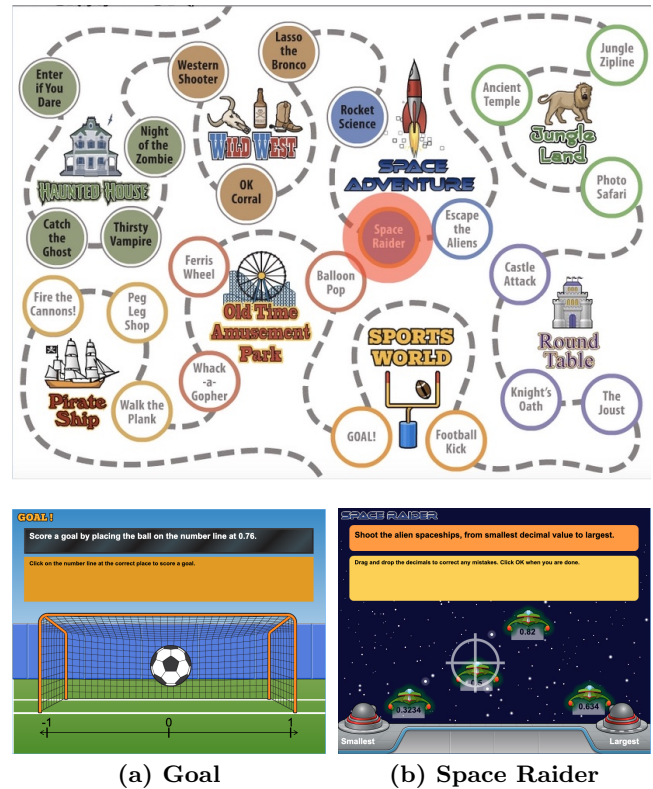

Figure 1: Screenshots of the main map screen and two example mini-games. Goal is a Number Line game and Space Raider is a Sorting game.

In each mini-game, students solve a number of decimal problems related to the game's targeted skill and receive immediate feedback about the correctness of their answers. Students don't face penalty on incorrect responses and can re-submit answers as many times as needed; however, they are not allowed to move forward without solving all the problems in the mini-game. More details about the instructional content of the mini-game problems can be found in [35].

The original study of *Decimal Point* showed that the game led to more learning and enjoyment than a conventional tutor with the same instructional content [35]. Subsequent studies have integrated the element of agency into the game, by endorsing students to select their preferred mini-games to play and stopping time [18, 39]. Based on their findings, students who were provided agency acquired equivalent learning gains in less time than those who were not. Most recently, a study by [22] compared two versions of the game, one that encourages students to play to learn, and one that encourages them to play for fun. Their results indicated that the learning-oriented group focused on re-practicing the same mini-games, while the enjoyment-oriented group did more exploration of different mini-games. In general, while all of these previous works reported that students learned from the game across all study conditions, it is not yet clear which game factors contributed to these findings. Furthermore, no connection between students' learning and their enjoyment has been identified. Our work aims at acquiring more insights into these areas.

Table 1: Survey items before and after game play.

Pre-intervention surveys		
Dimension (item count)	Example statement	Cronbach's α
Decimal efficacy (3) [44]	I can do an excellent job on decimal number math assignments.	.83
Computer efficacy (3) [31]	I know how to find information on a computer.	.71
Identification agency (2) [50]	I work on my classwork because I want to learn new things.	.60
Intrinsic agency (2) [50]	I work on my classwork because I enjoy doing it.	.86
External agency (3) [50]	I work on my classwork so the teacher won't be upset with me.	.61
Perseverance (3) [12]	Setbacks don't discourage me. I don't give up easily.	.79
Math utility (3) [13]	Math is useful in everyday life.	.63
Math interest (2) [14]	I find working on math to be very interesting.	.75
Expectancy (1) [23]	I plan to take the highest level of math available in high school.	-
Post-intervention surveys		
Dimension (item count)	Example statement	
Affective engagement (3) [5]	I felt frustrated or annoyed.	.78
Cognitive engagement (3) [5]	I tried out my ideas to see what would happen.	.54
Game engagement (5) [7]	I lost track of time.	.74
Achievement emotion (6) [43]	Reflecting on my progress in the game made me happy.	.89

3. DATASET

Our work uses data from 159 fifth and sixth grade students in our prior study [22], where students could select and play the mini-games from the map in Figure 1 in any order, and were allowed to stop playing at any time after finishing 24 mini-game rounds. They could also play more rounds of the completed mini-games, with the same game mechanics but different question content. For example, the first round of the mini-game *Goal* asks students to locate 0.76 on the number line, while the second round features the same game interactions but involves locating 0.431. Before playing, students did a pretest and answered demographic survey questions. After game play, they completed another survey to evaluate their experience and did a posttest, followed by a delayed posttest one week later. Here we outline the measures which are relevant to our analyses. A more detailed description of the experimental design can be found in [22].

Pretest, Posttest, and Delayed Posttest: Each test consisted of 43 items, for a total of 52 points. The items were designed to probe for specific decimal misconceptions, and involved either the five decimal skills targeted by the game or conceptual questions (e.g., “is a longer decimal larger than a shorter decimal?”). There are three test versions (A, B and C), which are isomorphic to one another and counterbalanced across students (e.g., ABC, ACB, BAC, etc. for pre, post, and delayed). Our prior analysis showed no differences in difficulty between the three versions [22].

Questionnaires: Before game play, students reported their age and gender, as well as their ratings to survey items about their background information, from 1 (“Strongly Disagree”) to 5 (“Strongly Agree”). After playing, students rated their

enjoyment (also from 1 to 5) via survey questions that address four enjoyment dimensions (Table 1). If a dimension comprises several items, we compute the average ratings of all items in that dimension to derive its representative rating score. According to [16], a measure should have $\alpha \geq .60$ to be considered reliable; therefore, based on Table 1 we removed the cognitive engagement dimension (with $\alpha = .54$) from further analyses.

The full log data from the study is archived in the DataShop repository [55], in dataset number 3086. We present our analysis of this data in the following section.

4. RESULTS

4.1 Investigating in-game learning

In our prior work on Knowledge Component (KC) modeling in *Decimal Point*, based on data from a separate study, we used the correctness of the student's first attempt in answering each mini-game problem to update their mastery of the KC covered by that mini-game. With this mapping from in-game action to KC, we found that students' learning can be better captured by a KC model based on skill types (e.g., *Addition*, *Bucket*) than on decimal misconceptions (e.g., *Segz*, *Negz*) [40]. Therefore, in this work we used the five skill types as our KCs, and tracked students' learning progress of these skills by Bayesian Knowledge Tracing (BKT) [60]. The BKT parameters were set as $p(L_0) = 0.4$, $p(T) = 0.05$, $p(S) = p(G) = 0.299$ [3], and the mastery threshold is 0.9.

First, we looked at how well students mastered each of the five skills in the game. Comparing the students' final mastery probabilities in each skill and our mastery threshold,

we observed that: there were 4 students who did not master any skill, 20 students who mastered one skill, 33 students who mastered two skills, 42 students who mastered three skills, 34 students who mastered four skills, and 26 students who mastered all five skills. Next, we counted how many opportunities each student who mastered a skill took to reach mastery in that skill. An opportunity is defined as one complete decimal exercise; each mini-game round consists of one opportunity, except for those in **Sequence**, which contain three opportunities (i.e., students have to fill in three decimal sequences per round). The distributions of opportunity count until mastery are plotted in Figure 2, which shows that **Number Line** and **Sorting** took the longest to master, at around 5 opportunities on average. For **Number Line**, one student even needed 26 opportunities to reach mastery.

Figure 2: Opportunity counts until mastery for each skill. The number next to each skill indicates the count of students who mastered that skill and were included in the violin plot.

Next, we examined how well students regulated their learning, i.e., after mastering a skill, did they tend to continue practicing the same skill, or switch to a different skill? For each student, following [8], once they mastered a skill ($\geq 90\%$ mastery probability), we considered their subsequent opportunities as over-practice. Then, for each student who mastered a particular skill, we computed the ratio between their over-practice count and total opportunity count in that skill. Plotting these ratios for all the mastered students in each skill (Figure 3), we observed that between 20-80% of a student’s practice opportunities in a skill could be considered over-practice, i.e., they took place after the student had mastered the skill.

4.2 Investigating factors related to posttest and delayed posttest performance

Having examined students’ in-game learning, we then looked at how it related to test performance after the game. In order to predict posttest and delayed posttest scores, we collected features that reflected students’ in-game learning and also included demographic measures that account for individual student differences. In total, we considered 19 features: pretest score, decimal efficacy, gender, computer efficacy, identification agency, intrinsic agency, external agency, perseverance, utility, math interest, expectancy, final in-game mastery probabilities of the five skills (**Addition**, **Bucket**, **Sequence**, **Number Line**, **Sorting**), total opportunity count, over-practice opportunity count and total incorrect answer counts. To identify the most important features, we (1) per-

Figure 3: Over-practice ratio in each skill. The number next to each skill indicates the count of students who mastered that skill and were included in the violin plot.

formed feature selection with linear regression, and (2) ran another linear regression model with the selected features on the full dataset to inspect the coefficient and significance of each feature. In step (1), we use the `mlxtend` library [45] to run a forward feature selection procedure that returns the feature subset with the best cross-validated performance, measured in terms of mean squared error (MSE).

In predicting posttest scores, our feature selection identified three features: **Bucket** mastery, **Sorting** mastery and pretest score. A linear regression model with these three features, when trained and evaluated on the entire dataset, had an MSE of 26.167 and an adjusted R^2 of .735. Based on the regression table, the coefficient and significance of each feature was as follow: pretest score with $\beta = 0.734$, $p < .001$, **Bucket** mastery with $\beta = 6.833$, $p < .001$, **Sorting** mastery with $\beta = 5.100$, $p = .001$. In other words, pretest scores, **Bucket** mastery and **Sorting** mastery each had a positive and significant association with posttest scores.

The delayed posttest model incorporated two additional features – **Number Line** mastery and gender – and yielded an MSE of 24.218, as well as an adjusted R^2 of .747. Based on the regression table, the coefficient and significance of each feature was as follows: pretest score with $\beta = 0.730$, $p < .001$, **Bucket** mastery with $\beta = 4.276$, $p = .018$, **Sorting** mastery with $\beta = 4.270$, $p = .003$, **Number Line** with $\beta = 3.099$, $p = .029$, and gender with $\beta = 1.426$, $p = .074$. In other words, the three skill mastery values – **Bucket**, **Sorting**, **Number Line** – as well as pretest score each had a positive and significant association with delayed posttest score, while gender (male = 0, female = 1) had a positive and marginally significant association.

4.3 Investigating factors related to enjoyment

For each enjoyment dimension measured in post-intervention surveys (achievement emotion, game engagement, affective engagement - see Table 1), we computed the per-student average Likert scores to the statements in that dimension. Then, we performed the same feature selection procedure as in 4.2 and reported our results in Table 2.

We observed that the adjusted R^2 values of the game engagement and affective engagement models were much lower

Table 2: Results of feature selection for predicting game enjoyment. The Overall performance row indicates the selected model’s scores when trained and evaluated on the entire dataset.

	Achievement Emotion	Game Engagement	Affective Engagement
Selected features	computer efficacy, identification agency, intrinsic agency, math interest, pretest score, total opportunity count	math interest, computer efficacy, gender	decimal efficacy, gender, intrinsic agency, Sorting mastery, Bucket mastery, total incorrect attempt count, identification agency
Overall	MSE = 0.520	MSE = 0.602	MSE = 0.660
performance	Adjusted R^2 = 0.386	Adjusted R^2 = 0.225	Adjusted R^2 = 0.218

than those of the test score models. Even when trained and evaluated on the entire dataset, Linear Regression could only explain about 20% of the variance in game engagement and affective engagement. On the other hand, the achievement emotion model did have reasonable performance (adjusted R^2 = .386), so we focused on analyzing the features in this model. The linear regression table showed the coefficient and significance of each feature as follows: computer efficacy with β = 0.047, p = .063, identification agency with β = 0.099, p = .024, intrinsic agency with β = 0.116, p = .002, math interest with β = 0.114, p = .001, pretest score with β = -0.017, p = .011, opportunity count with β = 0.009, p = .033. In other words, computer efficacy had a positive and marginally significant association, while pretest score had a negative and significant association; the remaining features (identification agency, intrinsic agency, math interest and opportunity count) each had a positive and significant association.

5. DISCUSSION

5.1 Investigating in-game learning

Based on the opportunity count until mastery in each skill (Figure 2), we identified **Sorting** and **Number Line** as the most difficult skills in the game. Our prior learning curve analysis [40] on a different *Decimal Point* study reported a consistent finding – that the learning curves of these two skills were mostly flat and reflected small learning rates. Based on previous research in decimal learning, a plausible explanation is that there are several misconceptions which can lead to students making a mistake in **Sorting** or **Number Line** problems, including (1) treating decimals as whole numbers, (2) treating decimals as fractions, and (3) ignoring the zero in the tenths place [46]. Furthermore, even when students recognize their misconception, they may shift to a different misconception instead of arriving at the correct understanding [56]. This phenomenon likely also occurred in *Decimal Point*, as the game provides corrective feedback (whether an answer is right or wrong) but does not emphasize the underlying reasoning; consequently, as an example, a student realizing it is wrong to assume longer decimals are larger may end up concluding that shorter decimals must be larger, thereby adopting a new misconception. This highlights the need for more refined tracing of the student’s dynamic learning states in a digital learning environment. While the standard KC modeling technique can track when students make an intended mistake (e.g., longer decimals are larger), it does not investigate their specific input to see whether a new misconception (e.g., shorter decimals are larger) has emerged. To address this issue, future itera-

tions of the game should provide more instructional support that can react to various misconceptions from students, for example via explanatory feedback [19] or predefined error messages for different types of error [36].

Once students have mastered a skill, however, our analysis showed that over-practice was very common, i.e., students kept playing more mini-games in the mastered skill. At the same time, there were only 26 out of 159 students who mastered all five skills, suggesting that the majority of students still had room for improvement in the unmastered skills but chose not to practice them. One possible reason is that the game environment did not explicitly indicate when the student has reached mastery or force them to switch to practicing a different skill. Consequently, young students, who were likely to be weak at self-regulated learning [37,53], simply played the mini-games that they thought were engaging, which in this case involved the skills they had already mastered. A prior study by [29] similarly found that, in a game about locating fractions on number line, students were more engaged when the game was easier, contradicting game design theories that optimal engagement would occur at moderate difficulty level.

5.2 Investigating factors related to posttest and delayed posttest performance

We saw that our linear regression models were able to predict posttest and delayed posttest performance well, capturing about 75% of the variance in test scores with only 3-5 features. The three features present in both models are pretest score, **Sorting** mastery and **Bucket** mastery. The inclusion of pretest score is not surprising, as it is consistent with the standard practice of controlling for prior knowledge when analyzing posttest score [58]. On the other hand, both **Sorting** mastery and **Bucket** mastery suggest that the ability to compare decimal numbers plays a large role in test performance. This is likely due to the game and test materials focusing on the four most common decimal misconceptions (Megz, Segz, Pegz, Negz), three of which are related to decimal comparison [25]. Based on the distribution of practice opportunities until mastery, however, students took much more attempts to master **Sorting** problems than **Bucket** problems, which may explain why they did not achieve high scores on the posttest and delayed posttest, averaging at only around 30 out of 52 points [22]. Therefore, improving students’ performance on **Sorting** problems, potentially by incorporating hints and error messages as we previously discussed, is crucial in future studies of the game.

At the same time, we saw that **Number Line** mastery had a significant positive association with delayed posttest score, but was not selected in the posttest model. An interpretation of this result is that **Number Line** tasks, which we identified as among the most difficult in the game, could be at a *desirable difficulty* level, which can promote deeper and longer-lasting learning than the more straightforward tasks [61]. For instance, a prior study on comparing erroneous examples and problem-solving decimal tasks found that erroneous examples, which are more aligned with the desirable difficulty, led to significantly higher delayed posttest scores but similar posttest scores [34]. In our case, we also saw that **Number Line** is an important feature for predicting delayed posttest but not for predicting posttest performance.

Similar to **Number Line** mastery, gender (male = 0, female = 1) was not a feature in the posttest model, but had a positive association with delayed posttest scores. In other words, with other factors being equal, females could achieve higher delayed posttest scores than males. While this association is only marginally significant ($p = .074$), similar findings about females' tendency to outperform males in retention and delayed posttest have been reported in previous mathematics intervention studies [1, 20]. Using the same dataset as in this work, [22] also found that females demonstrated significantly higher pre-post and pre-delayed learning gains than males, with a larger effect size in pre-delayed learning gains. Therefore, an important next step is to conduct future studies of *Decimal Point* on a larger sample size to draw more conclusive findings about whether the game promotes more retention in females and what could lead to this effect.

5.3 Investigating factors related to enjoyment

Our enjoyment prediction models did not perform as well as the learning models and could explain only about 20% of the variance in game engagement and affective engagement. These poor model fits likely result from the lack of appropriate features in our data. To track student engagement, previous work has emphasized the use of fine-grained measures such as time spent on decision making [47], social engagement profile [49] and interaction traces [6]; in contrast, our feature set consists mainly of quantitative scores (e.g., Likert responses) and aggregate data (e.g., error count). Related to this direction, a previous study of *Decimal Point* by [57] has clustered students based on their mini-game selection orders and found that the cluster which demonstrated more agency reported higher enjoyment. Adopting their method of encoding students' mini-game sequences is a good first step in building more fine-grained features for our prediction tasks. On the other hand, the lack of association between our in-game learning measures (e.g., skill mastery, over-practice opportunity count, error count) and game engagement or affective engagement implies that students' game performance, whether good or bad, were unlikely to yield any negative emotion such as confusion or frustration. This is a positive outcome, indicating that our game environment does not impose any performance pressure on students – one of the primary principles of learning games [15].

At the same time, we did find that a linear regression model was able to predict achievement emotion reasonably well from student's identification agency, intrinsic agency, math interest, computer efficacy, pretest score and opportunity

count. Identification and intrinsic agency indicate that, with all other factors being equal, the more students identified their learning as coming from intrinsic motivation (rather than external pressures), the more achievement they felt after learning. Math interest and computer efficacy suggest that students' acquaintance with the learning domain or medium could also be positively associated with achievement emotion [26]. On the other hand, pretest score had a negative association, likely because students with lower prior knowledge were able to learn more from the game and therefore felt more achievement than those with high prior knowledge. Similarly, for opportunity count, a plausible reason for students choosing to play more mini-game rounds is that they felt the mini-games were helpful, which contributed to their achievement emotion after game play. Overall, the features we identified could serve as a guideline for promoting achievement emotion in learning games and in more general instructional contexts.

6. CONCLUSIONS

From our analyses, we gained several insights into students' learning outcomes and enjoyment in *Decimal Point*. First, we found that **Sorting** and **Number Line** are important skills for posttest and delayed posttest performance, but students required more instructional support to effectively master them. Second, very few students mastered all five decimal skills from the game, while the majority engaged in over-practice, likely due to their preference for playing easy mini-games, i.e., those they had already mastered. Third, expanding on prior findings about gender effect in *Decimal Point* [22, 33], we identified a trend of females outperforming males in the delayed posttest, which should be investigated on a larger sample size. Fourth, we learned that students' achievement emotion can be reasonably captured by their level of computer efficacy, learning motivation, prior knowledge and number of mini-game rounds. All of these insights can be derived from log data alone and would serve as useful metrics to assist digital learning game researchers in evaluating and improving their own games. For *Decimal Point*, in particular, an important next step is to perform similar analyses in other studies of the game to see which of our findings can be replicated. Identifying consistent trends in student data could allow us to construct a more generalized model of students' game play that combines existing theories with novel exploratory analyses [38].

In a broader context, we have seen the rapid growth of digital learning games in recent years, from being conceived as a novel learning platform [15, 21] to having their effectiveness validated by rigorous studies [10]. The game *Decimal Point*, in particular, has been shown to significantly improve students' learning through several research works [18, 22, 35, 39]. When viewing from a learning analytics perspective, however, one could identify room for improvement that would otherwise not be reflected in pretest and posttest scores alone. For instance, a game may not adequately support all of its learning objectives, or students may engage in non-optimal learning behavior due to a lack of self-regulation. At the heart of these issues is the question of how digital learning games can optimize student learning while retaining its core value as a playful environment, where players are free to exercise their agency. Addressing this question is an important step for future works in the field.

Measuring Ability-to-Learn Using Parametric Learning-Gain Functions

Chris Piech, Engin Bumbacher, Richard Davis
Stanford University
piech@cs.stanford.edu, rldavis@stanford.edu

ABSTRACT

One crucial function of a classroom, and a school more generally, is to prepare students for future learning. Students should have the capacity to learn new information and to acquire new skills. This ability to “learn” is a core competency in our rapidly changing world. But how do we measure ability to learn? And how can we measure how well a school has prepared their students to learn? In this paper we formally pose the problem, and introduce a grounded theory of how to measure ability to learn. Using simulations of students learning we provide initial evidence that this theory provides an elegant solution to this problem. We further validate our ideas using real world data from 70k middle-school students and show that our theory is more accurate and interpretable than current state-of-the-art models of learning gains. We consider our results a modest yet interesting first step for a novel type of test.

1. INTRODUCTION

Large-scale, standardized tests typically measure knowledge and skills that students already possess, such as reading comprehension and mathematical competency. However, these tests overlook students’ abilities to acquire new knowledge and skills. Could we instead measure how well a student is able to *learn*? Measuring how well a school system has prepared a student for learning is a particularly hard challenge and as such it remains elusive. PISA (Programme for International Student Assessment – an international test run every three years to evaluate educational systems), has made it a goal of their 2024 innovative assessment to measure ability to learn. How could such a test be scored?

Early research has shown that measuring ability to learn is both important and difficult. Work by Schwartz et al. [18, 17, 19] has shown that assessments of students’ ability to learn capture important information that assessments which simply measure what a student knows fail to capture. In these studies, students participated in two different educational interventions, one designed to teach students factual content

in a manner that also prepared them for future learning, and one designed to teach students factual content using more traditional approaches. Standard measures of knowledge found that regardless of the intervention, students in both groups learned the same factual content. However, a second type of assessment designed to measure students’ ability to learn uncovered significant predictive differences.

Despite the potential, to the best of our knowledge, there are no large-scale assessment that have attempted to measure students’ ability to learn. In traditional tests, students get questions correct or incorrect — a single random variable that is traditionally modeled using Item-Response Theory (IRT). In a learning test, on the other hand, students work through learning experiences which produce two measurable values: a **prior (pre)** and **posterior (post)** ability. All learning experiences, especially relevant authentic ones, are impacted by what a student knows when they start. A useful model would enable measurement of student learning across countries, schools-districts, and millions of students as they engage in a necessarily wide variety of learning experiences. Without a useful model it is hard (if not impossible) to produce desired and important analyses such as: (a) inferring ability to learn from multiple learning experiences (b) discovering issues of fairness in learning experiences (c) reasoning about mixture effects within populations.

The prior-knowledge confound: Measuring learning-ability is particularly difficult because it requires us to reason about the impact of prior knowledge. For example, consider two populations where students have the exact same ability to learn but different levels of prior knowledge. Now imagine the two populations are given the same learning experience. Both populations will learn (recall they have the same learning ability) but will have different outcomes on the same exam. In practice most people model this relationship using a “linear” model [22]. However, research has shown that the impact of prior ability has important non linear properties [21, 15]. This is an instance of Simpson’s Paradox.

A core insight of this paper is to think of the difference between prior and posterior ability as being governed by population specific parametric functions which we call **Learning-Gain Functions**. These learning gain functions are naturally incorporated in a fully Bayesian model of student responses on learning ability tests. The main contributions of this paper are:

1. We formalize, parametric Learning-Gain functions as a

Chris Piech, Engin Bumbacher and Richard Davis "Measuring Ability-to-Learn Using Parametric Learning Gain Functions" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 496 - 502

way to model ability-to-learn tests.

2. We introduce an interpretable single-parameter Bayesian family of Learning-Gain functions.
3. We show that this model is able to near-perfectly recover learning ability in a complex, simulated dataset.
4. We demonstrate that this model outperforms other single- and multi-parameter models on two real-world datasets.
5. We show the practical value of this model by comparing real-world schools on their “ability to learn” as estimated by our model

This work is a first attempt at addressing the need for models of student “ability to learn” that can be employed in large-scale assessments such as PISA 2024. The initial results are promising, and we hypothesize that the model will generalize broadly to different learning tests.

1.1 Population Learning-Ability Tests

Learning-ability-tests are built to directly measure the “ability to learn” of a population. The most straightforward format for such an exam has learners complete a set of learning tasks and for each task j , the learner i is given a pre and post test – these fence-post the learning gains. We define alpha ($\alpha_{i,j}$) to be a student’s prior ability on the task and beta ($\beta_{i,j}$) to be the student’s posterior ability.

We seek to measure ability-to-learn for a population (or an individual as a singleton population) as a number, which we call θ . This measure should generalize and explain ability-to-learn of the population on a different learning-task. In order to learn a generalizable θ we must learn to separate ability-to-learn from task specific effects (such as if the task is easier for beginners to learn than for advanced students etc). We use the notation phi (ϕ_j) to represent task specific parameters for task j .

We propose that when a student engages with a learning task, the learning-ability of the student (θ) interacts with task-specific-parameters (ϕ_j) to produce a **learning-gain-function** (f_j) which determines how prior-abilities will map to post-abilities. As such a function oriented probabilistic model of a single student, from a population with learning-ability θ , working on a series of learning tasks would look like the following:

Learning-ability tests stand in contrast to Intelligence Quotient (IQ) exams as measurement takes place on either end of a learning experience. IQ tests on the other hand measure aptitude, and while this often requires learners to engage in complex tasks the goal is to measure ability on the task.

1.2 Prior work

This work builds on a rich and broad literature of work on measuring ability-to-learn which extends for decades [5, 13, 9]. Evaluation of students’ ability to learn is often treated as equivalent with change in knowledge over time, typically with a pretest and posttest. Common approaches include comparison of raw gain scores (posttest minus pretest), analysis of posttest scores with pretest scores as a covariate, and analysis of gains scores with pretest scores as a covariate. Each of these methods has strengths and weaknesses, although there is evidence that analysis of gain scores with pretest scores as a covariate is the best of these methods when certain assumptions are met [6]. As such, we included this model (Linear Multi-Theta) in our model comparison on real-world data and find that it doesn’t fit as well. Additionally, while the intercept and slope parameters in the Linear Multi-Theta model can be interpreted as describing a population’s ability to learn, it is not immediately clear how they might be used to compare different populations. Both the Learning-Gain-Decay and Learning-Gain-Bump models estimate ability to learn with a single parameter, avoiding this problem. Taken together, these factors suggest that it would be prudent to move away from the Linear Multi-Theta model if our goal is to estimate ability to learn.

Another approach to estimating student ability to learn is to characterize “learning curves” [7]. This requires repeated sampling over time so the learning rate can be determined from the shape of the curve, where students with higher ability to learn are characterized by steeper learning curves, and students with lower ability to learn are characterized by shallower curves. However, the shape of a learning curve does not reveal the full interaction between prior and posterior knowledge. We would expect two students with the same ability to learn but different levels of prior knowledge to progress at significantly different rates. Additionally, collecting enough data to plot a learning curve requires repeated measurement that is infeasible in most educational settings.

NWEA has looked into how to quantify learning gains [12, 11] and most recently [21]. Their contemporary models project student abilities into norm grade levels. [16, 8]. Anderman et al make initial steps into translating learning-gain research into a bayesian model [1]

Significant research has focused on the promise and perils of using student gain data as an outcome—as a good indicator of teacher effectiveness. There is a book on the subject of evaluating teachers by measuring their value added: Evaluating Value-Added Models for Teacher Accountability [10]. We remind the reader that it is necessary to be careful and accurate in measuring student learning.

There is a rich mathematical history of reasoning about functional mappings. This field of mathematics draws from domains as diverse as 3D geometry [14, 3] to neocortical circuitry [20]. This is, to the best of our knowledge, the first use of functional maps in measuring learning.

1.3 Learning Gain Functions

In traditional IRT, each interaction between a student and a question (aka item) produces a single number. In a learning test, each learning-experience produces two numbers ($\alpha_{i,j}$

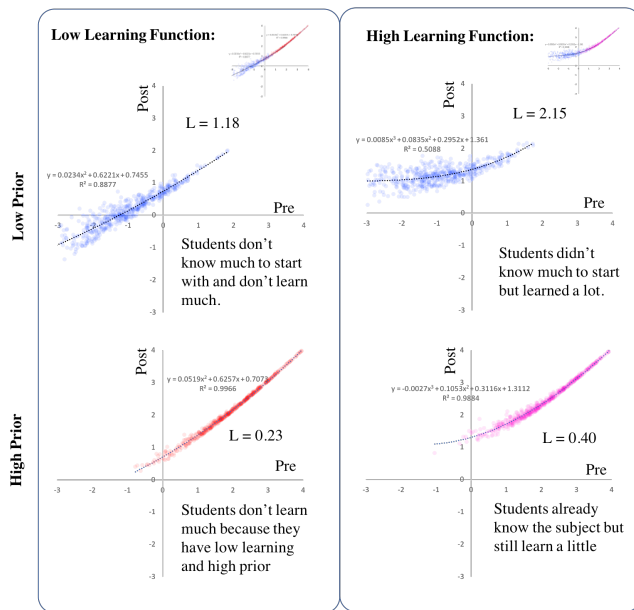

Figure 1: Simulations of four populations on the same task. Each graph represents pre/post abilities for one population. Each point represents one student. Countries in the columns have the same learning function. $L = \mu$ post minus pre.

and $\beta_{i,j}$). This poses a modelling challenge. How do we model learning, in a way that elegantly considers the effect of prior knowledge ($\alpha_{i,j}$)?

We found it natural to resolve this problem by thinking of the learning experience as being a reflection of an underlying *function* which we call learning-gain-function. A learning-gain-function is a population wide mapping of student pre-conditions to post-conditions. In a learning-ability-test, we would like to compare populations on their ability to learn, and as such it seems like it would be best to compare the countries by their functional mapping. Thinking of the mapping of prior-ability to post-ability is incredibly useful if we want to build a Bayesian model of learning-ability.

To articulate this point, consider the four different populations learning on the exact same learning task (Figure 1). For all four populations we plot prior abilities and posterior abilities. The two populations on the left both have the same learning “function” on this task. If you had two students with the same prior ability, after the learning-task they would have (within noise) the same post ability. As a confound, they have different prior ability distributions. Typical measures of learning gains would compare these two populations based on the average difference in post ability versus pre ability (L shown on the figure). *As such they would look very different even though the two populations have the same learning-gain-function.* The same is true for the two populations on the right. They also have the exact same learning-gain-function, but as a result of different prior knowledge distributions, typical metrics make them seem quite different. By modelling a learning-gain-function we neither benefit, nor penalize populations for having different prior distributions. Instead we compare learning in a way that is agnostic to previous knowledge.

The learning function f is “parameterized” by the ability-to-learn parameter θ and task specific parameters, ϕ :

$$f_{\theta_i, \phi_j}(\alpha_{i,j}) \rightarrow \beta_{i,j}$$

In the case of PISA, this theta should represent “ability to learn” for a specific population. The function, importantly, does not have to be linear – and in fact ample evidence shows that it should not be. Note that, $\alpha_{i,j}$ and $\beta_{i,j}$ can be estimated using standard item-response theory.

This formalization lends some insight into how we can deal with the different levels of prior knowledge between populations. At this point we haven’t made any claims about what the function looks like. What is an appropriate parametric form of a learning-gain function?

2. SIMULATING LEARNING

To begin the process of understanding the family of functions for how much students learn during a task, we built a series of simulators in python that attempt to match as realistically as possible the process of learning during a task. The simulator has fake students learn through the process of working on fake items, where the learning and progress at each minute is governed by the interaction between a student’s prior knowledge and the difficulty of the items (an assumption loosely based on the zone of proximal development). This simulation is not perfect, but it provides us with a starting point for building a theory of ability to learn. It is simple, and makes it possible to observe all the factors that impact changes in knowledge, including variables which are often unobservable like learning ability.

These simulations have the added benefit of building a falsifiable condition for any model which tries to estimate ability to learn. I.e., any good model should be able to describe this synthetic data. While ability to describe synthetic data is evidence in support of a theory, it is a necessary but not sufficient condition. The final test would be to show that it also works with real world data.

Figure 1 shows a simulation of 2,000 students learning in four countries via a single task which is heavily biased towards “beginners learn more”. The countries in the right column both have the exact same learning function, but because their students have different priors, they are very hard to distinguish that they have the same learning ability.

The main take away at this point is to confirm what we believed from prior work: average “ability” gain is not a very useful metric. Even for countries with the exact same learning rate we observe very different average gains (L) when priors are different.

3. THEORY OF LEARNING FUNCTIONS

If we could come up with an equation for that function (aka the form) we could formalize our measurement of ability-to-learn. In the example from Figure 1 it feels like a “polynomial” fits f well – but that turns out to be a bit misleading. The learning-experience in that figure represents one where “beginners learn more.” If we change the learning task to be one where “medium level students learn more” the function is not well fit by a polynomial.

Figure 2: The same population on three different tasks. Left: a task on which beginner students learn more. Middle: a task on which medium students learn more. Right: top students learn more. Points are simulations pre-vs-learn of different students.

If we revisit our simulations and consider “pre vs learn-delta” as opposed to “pre vs post” we can gain insight into the functional form. Here we define learn-delta to be an individuals improvement from post to pre on the learning-task ($\beta_j - \alpha_j$). Figure 2 shows the “pre vs learn-delta” for three different tasks, produced by the simulation, one where beginners learn more, one where medium students learn more, and one where students with advanced prior knowledge learn more.

The graph in the middle (medium students learn more) resembles a “Gaussian” bump, whereas the graphs on the left and right look like exponential decay and growth, respectively. However, upon further inspection, we note that all of the graphs can be represented by an equation with a Gaussian bump. The exponential graphs could be considered to be left and right legs of a bump.

In order to build a functional form that matches all three scenarios (while appreciating that the “beginners learn more is much more common”) we propose a simple parametric form which can describe all three, the learning-gain function family:

Learning-Gain-Bump Family: The function of a student i from population j with learning ability θ , learning on task k with parameters ϕ is:

$$f_{\theta,\phi}(\alpha) = \alpha + \theta \cdot e^{-\frac{(\alpha-\phi_1)^2}{\phi_2}} = \beta \quad (1)$$

Where:

- α is prior ability of student i on task k
- β is posterior ability of student i on task k
- θ is “ability to learn” of population j
- ϕ is a vector of two task k specific constants.

In this model larger values of learning-ability (θ) scale up the Gaussian shaped bump.

We note that in practice most learning experiences tend to have the property that “beginners learn more” and as such an exponential decay function should often work well in practice. As such we also consider the Learning-Gain-Decay Family: $f_{\theta,\phi}(\alpha) = \alpha + (\alpha + \phi_1)^{-1} + \phi_2$

Inference is performed using a PyTorch implementation of the model, and Adam optimization to minimize the Mean Squared Error in predicting posterior (β) abilities.

4. EVALUATION

While the Learning-Gain function family seems reasonable as a hypothesis. In order to test its utility as a basis for item response theory on learning-ability, we evaluate on both simulated data with known learning-abilities and real-world data.

4.1 Simulated Evaluation

To evaluate we generated two tasks, and for each task simulated 2000 students from eight countries with a range of parameters: most importantly a single parameter which represented the latent ability to learn of a student from that population.

To evaluate, we build an inference algorithm to take the observed data produced by the simulations (the pre/post abilities of each student) and attempt to infer single value θ_j for each population j using the generative model in Equation 1. Recall that the simulations are **not** generated from our assumed function, rather it is a product of a zone-of-proximal development rather-complex simulation.

The Bayesian model, which estimates learning-ability via learning-gain-functions, is able to perfectly back-out “population ability to learn” from such simulated data (For both tasks with eight countries, $R^2 > 0.99$). In contrast a linear function was not able to fit the data nearly as well. For the task that was good for beginners it performed reasonable ($R^2 = 0.92$) whereas for the task that was good for medium prior knowledge the model was predictably unable to fit the data ($R^2 = 0.81$). While this is impressive result especially considering the complexity of the simulation, in order to consider this model useful we would like it to be able to make predictions on real-world data.

4.2 Evaluation on Real-World Data

We trained the Learning-Gain-Fn model on two real-world datasets: NWEA and ECDL. The NWEA dataset contains 69612 students from 330 schools in Grade 7 whose reading level was assessed twice (pre test and post test) using item-response theory, once in Winter and again in Spring 2017. The ECDL dataset contains data from 379 undergraduate students at the University of Alcalá (Spain) [4]. Scores for each student include four pretests and four posttests corresponding to distinct learning modules.

We compared the Learning-Gain-Fn model to a number of other plausible models: a linear model, a second-order polynomial, an exponential-decay model, and a linear model

Table 1: Results on Real-World Data

Model	Parameters per Population	Formula	NWEA Test-Set MSE	ECDL Test-Set MSE
Linear	1	$\Delta_i = \alpha_i \phi_1 + \theta_j$	56.9	0.45
Polynomial	1	$\Delta_i = \phi_1 \alpha_i^2 + \phi_2 \alpha_i + \theta_j$	56.0	0.47
Learning-Gain-Decay	1	$\Delta_i = \theta_j (\alpha_i + \phi_1)^{-1} + \phi_2$	54.9	0.44
Learning-Gain-Bump	1	$\Delta_i = \theta_j \cdot e^{-\frac{(\alpha_i - \phi_1)^2}{\phi_2}}$	53.1	0.44
Linear Multi-Theta	2	$\Delta_i = \alpha_i \theta_{j_1} + \theta_{j_2}$	55.1	0.44

Figure 3: The simple model proposed by the Learning Gain Bump Family allows for very accurate prediction of latent ability to learn from the complex simulation.

with two parameters per population. (See Table 1 for model details.) Our primary goal was to identify a model that could best capture “ability to learn” in a *single parameter* across a variety of populations and testing scenarios. Estimation with a single parameter is important because it is more-easily interpreted—a higher value corresponds to a higher ability to learn. Each of the models we evaluated estimates “ability to learn” with a single parameter where higher values correspond to better learning ability. The exception to this rule is the Linear Multi-Theta model, which estimates ability to learn using two parameters. (See Related Work for an explanation of why this model was included.)

To compare models, we held out 10% of the data from each dataset and computed the mean-squared error when different

models made predictions about the missing data.

Notably, the Learning-Gain-Bump model outperforms all models on predicting held-out data, including the Linear Multi-Theta model. Full results are reported in Table 1. This suggests that “ability to learn” in these two cases followed a parametric form best explained by a more nuanced learning-gain function. While the gains in MSE are modest, we hypothesize that for some datasets, especially ones where the learning tasks most benefit medium strength students, the linear model will break down. We also note that the Learning-Gain-Decay and the Learning-Gain-Bump function performed very similarly – which indicates that all the tasks in this data were ones where ones where beginners learned the most.

Figure 4 shows the shape of the learning-gain-fn for different grade levels in the NWEA dataset between Winter and Spring. For every one of the 330 schools in the dataset we can now compute the ability-to-learn (θ) of the students in their population. We note that, as shown in Figure 4(b), the distribution of θ s appears to be Gaussian. Figure 4(a) also includes the learning-gain-fn for two of the top schools in the NWEA dataset. We note that it is impressive how much of ability-to-learn can be explained by which school a student went to. In the top schools (by learning-ability) students with low, medium and high prior ability substantially improve between the pre and post test.

These results are preliminary. The robust model of ability-to-learn presented in this paper will open up deeper analysis into learning in a wide range of contexts: from short tests of learning ability to evaluations of ability-to-learn in schools.

5. LIMITATIONS

Ability to learn is unlikely to be a single parameter: It is highly unlikely that a student’s ability to learn can be captured in a single number. However, this simplifying assumption proves to be convenient and useful. Often, the amount of data available to estimate parameters is small, making a model with few parameters attractive. Additionally, estimating ability to learn with a single parameter results in a model that is maximally-interpretable—the higher the number, the better the ability to learn.

There is a three-month gap between testing periods in the NWEA data: Our hypotheses about student ability to learn are based on a simulation of student learning that occurs over the course of a day. In testing these hypotheses we relied on real-world datasets that measured learning over

Figure 4: (a) NWEA pre-vs-learn graphs for different grade levels. Note that the distribution matches the theoretical simulated learning-task. The graph includes the pre-vs-learn for the school with the highest θ and the school with the highest θ for students with low prior ability. (b) shows the full histogram of learning abilities for different schools. (c) shows the relationship between student abilities and ability-to-learn

significantly-longer time period. For example, the two tests in the NWEA dataset that we used to measure ability to learn occurred approximately three months apart. Despite this fact, our model still fit the real-world data better than any alternative model, providing a measure of reassurance.

6. DISCUSSION

Modelling individual students’ ability to learn: The models in this paper estimate ability to learn at the group level. However, there are many cases where estimating individual students’ ability to learn would be useful as well. Due to the small number of datapoints per student, this could prove challenging. However, a hierarchical model that assumed individual students’ abilities to learn were governed by a strong group-level prior could overcome this problem.

Incorporating Pre/Post Tests: Given the function, we can incorporate this ability to learn into the traditional IRT process before and after. Specifically, the probability that a student i gets an item k right on the pre test should be, under the IRT-2PL: $p_{ik} = \sigma(\alpha_i - d_k)$ where d_k is the difficulty of item k and α_i is the same α_i that we used in our learning model. σ is the sigmoid function. Similarly the probability that student i gets a item k correct on the post test would be: $p_{ik} = \sigma(\beta_i - d_k)$ where β_i is the posterior ability of the student after the learning task. In the case where pre-post tests are real valued, we can use the logit-normal IRT proposed by Arthurs et al [2].

Fairness and Mixture Models: A Bayesian model of learning-gain-functions can do much more than simply infer ability-to-learn from pre-post tests. It would also allow for researchers to disentangle mixture distributions. This would allow researchers to identify sub-population effects within a larger population. Similarly, a robust model of ability-to-learn can be the basis of ensuring that a learning-task, and/or an education system is fair to different demographics.

Learning The Learning-Gain Function: In this paper we have modeled ability to learn as a parameter in a family of learning functions. This family of functions is Gaussian-like, a choice that was informed by observing the outcomes of a theoretically-grounded simulation. While this choice proved to have the lowest error, it is likely that another choice could offer improvements. Rather than trying a number of models,

each with its own assumptions, an alternative approach would be to use a small neural network to learn the model directly from the data.

Neural networks are universal function approximators, which means a small neural network should be able to learn the function family that serves as the best model that incorporates θ , ϕ , and α . Fears that neural networks are black-box algorithms that lack interpretability do not apply in this case—since the number of parameters is small, the learned function can be visualized directly across all values of the parameters. This approach would combine the flexibility of neural networks with the transparency and interpretability of the current models.

7. CONCLUSION

“Learning how to learn” is considered an essential skill for the 21st century [23]. Given the rapid pace of technological development, this is one of the most valuable skills an educational system can provide for its students. In recognition of this fact, the PISA 2024 test will contain an experimental section that has been explicitly designed to measure students’ ability to learn. However, few assessments have been explicitly designed to gauge this ability, meaning that the community lacks models that are capable of directly estimating this skill. In this paper we introduce a model that estimates student ability to learn using a single parameter. This model is more accurate at estimating student change in knowledge than other competing single- and multi-parameter models on two real-world datasets. Additionally, it is able to perfectly recover “ability to learn” from a complex, theoretically-grounded simulation of student learning over time. We present this work to demonstrate the value in explicitly modeling this skill, and we propose this model as a first step towards a more complete theory of understanding ability to learn.

ABSTRACT

Feature engineering, the construction of contextual and relevant features from system log data, is a crucial component of developing robust and interpretable models in educational data mining contexts. The practice of feature engineering depends on domain experts and system developers working in tandem in order to creatively identify actions and behaviors of interest. In this paper we outline a method of iterative feature engineering using the misclassifications of earlier models. By selecting cases where earlier models and ground truth disagree, we can focus attention on specific behaviors, or patterns of behavior, that a model is not using in its predictions. We show that iterative feature engineering on cases of false positives and false negatives improved a model predicting quitting in an educational video game by 15%. We close by discussing applications of this method for addressing model performance gaps across different classes of learners, as well as precautions against model overfitting with using this method of feature engineering.

1. INTRODUCTION

Educational games and digital simulations are powerful educational tools that have seen increasing use in classrooms within the last decade. These digital environments afford students rich opportunities to engage deeply with content, adopt new and different identities [6], explore personally relevant domains [8], and develop non-cognitive skills such as productive persistence [17]. The adoption of educational games as tools for learning has been accompanied with an increasing focus on educational games as a medium for the application of educational data mining. The medium of educational games presents challenges for EDM methodologies, however, as the relative complexity of student behaviors in games can be quite broad when compared to more constrained environments such as intelligent tutoring systems (ITS).

Given the more complex behaviors possible for students in these environments, researchers studying learning in digital environments and games are able to identify and predict more

complicated cognitive and non-cognitive constructs. Some examples of constructs identified in games include persistence [14], elegant problem solving [13], seriousness [5], carefulness [4], computational thinking [1], and mental demand [31].

This increased complexity places an increased importance on the feature engineering and/or knowledge engineering steps of the data science pipeline. Expert knowledge is often crucial for understanding specific patterns of behavior within educational games and simulations. For example, deep understanding of both gameplay design and conceptual understanding of physics were needed to develop a model of whether students had implicit conceptual understanding of physics based on how they responded to balls of different colors (connoting mass) in a physics game [22]. This understanding has driven feature engineering in many of these cases. Previous work by [23] has shown that feature selection and feature engineering of variables with high construct validity can lead to better model performance on unseen data. The question, then, is how we as researchers can quickly and effectively identify the specific patterns of player behavior that “matter” – how can we best separate the signal from noise in a large, complex dataset on student behavior and interaction?

Historically, social sciences researchers have addressed the complexity of human behaviors by combining qualitative methods providing “thick description” of actions [7] with quantitative methods to make scalable and general claims. However, the considerable amount of behavioral log data generated by modern learning systems poses a challenge to the qualitative analysis of human behaviors. One approach, termed “closing the interpretive loop” [24], is to refine and validate a model by looping back to the raw data, and checking whether the model and data are consistent. In an application of this method, [12] constructed a model to investigate how interactive indicators in the *Jaune Fluo* dataset relate to emotions in learning. By returning to and leveraging raw transcription data, they gained insights about micro-level interactions between speakers that could be used to drive modeling.

In this paper we propose a related approach -- a method for selecting specific cases of relevance from a larger dataset for further analysis, using instances of model mis-prediction. By adopting an iterative approach to model selection and feature engineering, we can use cases of false positives and false negatives to identify the specific cases where the model fails to accurately match student data, to better uncover relevant gameplay behaviors and patterns. We can then employ qualitative techniques to these cases to better understand what is occurring, and use these findings for additional feature engineering and model iteration. By closing the interpretive loop, we not only gain deeper understanding of the data, but also generate new contextual features for modeling in a way that is closely tied to observed patterns of behaviors in the data. We apply this method in the

Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 503 - 508

broader context of studying student quitting behavior in the educational physics simulation game *Physics Playground* [28].

2. METHODS

Data for this work comes from a series of randomized controlled trials (RCTs) conducted at middle schools in Pennsylvania and Florida during the spring of 2019 using the educational physics simulation game *Physics Playground*, courtesy of the *Physics Playground* team.

Physics Playground teaches elementary physics concepts such as conservation of momentum and torque through a sandbox environment where players are tasked with drawing simple machines that move a ball to a balloon elsewhere in the level. Students receive badges for successfully solving levels, and are able to use these badges to unlock different types of music, custom balls, and other cosmetic changes within the game. *Physics Playground* also contains in-game hints and scaffolds, accessible through a help button on the UI.

Figure 1. Physics Playground. The author has (unsuccessfully) built a lever and dropped a weight on it in an attempt to move the ball to the balloon. The help button (bottom right) and object counter (bottom left) are also pictured. The author would like to note that they are not a physicist.

A total of 96 students participated in the study. The RCTs were designed to test the effectiveness of several types of learning supports for *Physics Playground* on learning gains in the game. Students spent a total of ~110 minutes of class time playing *Physics Playground* in between a physics knowledge pretest and posttest, across four days. In the treatment condition, students were able to access a help button in the game UI that allowed the student to select multiple types of scaffolds to watch. Through the help button, students were able to receive help related to the use of game tools and mechanics, worked example solutions, and abstracted physics concepts. Students in the control condition were automatically prompted to use this button after three minutes had elapsed, but were unable to access the help button before that point. Preliminary analyses identified no significant differences in posttest scores or learning gains between conditions, so for the current study we combined these two groups and ignored condition assignment. Additional details on the study and its overall findings can be found in [29].

2.1 Data Structuring, Preprocessing, and Labeling

Gameplay data from the study were collected by the game's servers and output as .json files. A total of 703,765 records of student gameplay were collected during the study, where one record is a single logged student action in the game.

Several pre-processing steps were taken to prepare the data for analysis. Three students who did not complete the consenting process for the study were removed from the dataset. Events which occurred outside of study hours were also removed from the dataset. These events were due to students continuing to play the game in their free time. Attempts which were shorter than two seconds were also removed from the dataset. These attempts often consisted of students rapidly pressing the spacebar to reset their current level, without taking any in-game actions.

We also added additional contextual information into the dataset. We added the *Physics Playground* q-matrix into the dataset, which consists of the mapping between levels and physics constructs to be taught, as well as the simple machines associated with each level's solution. We added a series of session, visit, and attempt IDs to each record. A "session" is a length of time from student login to student logout. New sessions can begin when a student begins playing *Physics Playground* for the first time each day, or, when a student refreshes their browser. A total of 586 gameplay sessions were recorded, for an average of six sessions for each student. It is worth noting that students played the game for four days within the study; the higher average number of sessions is because students could accidentally refresh their browsers, or hit the "back" button, which began the logging of a new session. Within each session are "visits" – a visit lasts from the beginning of a level to the end of a level, whether the student solves that level successfully or quits to go to a different level. We identified 2906 total visits, with an average of 30 visits for each user – slightly less than the 34 levels available to play in the game for the current study. Finally, within each visit are "attempts" – an attempt begins any time that the level is initialized, and ends when a student either successfully solves the level, restarts the level, or quits the level. We identified 16,546 total attempts in the game, with an average of 172 for each user.

Given this structure of sessions, visits, and attempts, we defined a "quit event" as any time a student begins a new visit, within the same session, when their previous attempt was not successful. This represents a student failing to solve a level, leaving that level entirely, and playing a different level within the game. From each quit event, we labeled each record that happened up to 120 seconds before the event as "quit", and all other records as "not quit". Previous work on predicting quitting in *Physics Playground* used aggregations of 60-second clips within each attempt, e.g. [10]. In contrast, our method of labeling quitting at the event level, and up to 120 seconds prior, allows us to identify quitting across attempts, and sometimes across visits, in order to allow earlier detection and intervention by automated systems or in-classroom educators.

2.2 Initial Feature Engineering and Model Fitting

Drawing on previous literature that has explored *Physics Playground* [10,13], we developed an initial set of 32 features to use in predicting student quit behavior. These features included counts of each type of object or simple machine (weights, ramps, levers, pendulums, springboards, freeforms, and pins) that the student had drawn total and per attempt, the number of times students went some number of seconds without recording an action (5, 10, 15, 30, and 60 seconds), and whether students used each type of scaffold (worked examples, game tools, and physics animations) as well as the number of scaffolds that they used total and in each attempt. We also developed features to capture the amount of time that students spent using scaffolds, as well as the

amount of time that had passed (in seconds) since the last time a scaffold was used. Finally, we recorded the elapsed time of each attempt, as well as the total elapsed time of the session, and the number of badges that students had earned so far.

For modeling quit behavior, we chose to use a relatively simple logistic regression model rather than more sophisticated algorithms such as a decision tree, gradient classifier, or recurrent neural network. Regression-based models are easier to implement into *Physics Playground's* Unity-based architecture than more sophisticated machine learning models. We used five-fold student-level cross validation in RapidMiner 9.4 [15]. We did not use any feature selection procedures for modeling; each feature was used as a component in the final model. We did not believe that our feature space was large enough to warrant feature selection. We used AUC ROC as our goodness metric, as we were more interested in overall model performance than optimizing our quit prediction threshold.

This initial model, which we will call the “original” model with “original” features in this paper, has an AUC of 0.688.

2.3 Error Identification and Feature Re-Engineering

Using the confusion matrix of this initial model, we identified all false positives and false negatives and mapped these events onto the attempts in the dataset. In other words, if *any* record within an attempt contained a case of model mis-prediction, we labeled the entire attempt as a mis-prediction. This resulted in 1,487 attempts labeled as cases of false negatives (9% of all attempts) and 298 cases of false positives (2% of all attempts). We then used text replays [2] to qualitatively code these attempts for patterns of engagement or behavior that we believed could be related to quitting behavior in players. Text replays have been used previously to conduct in-depth study of other constructs such as gaming the system [19], as well as to obtain training labels for the development of detectors [21, 23, 5]. [19]’s research shows that they can be a powerful tool for developing thick descriptions of learner behavior, and that this deeper understanding can lead to substantially better models of that behavior [18]. We randomly selected 100 examples each of false positives and false negatives for this coding process and conducted text replays on these attempts, taking notes on potential new features which could capture behaviors that we observed in the data. This coding procedure was done by a single researcher. As in [19], reliability measures were not obtained, as the goal was to develop new features that could be applied to the data programmatically rather than to develop a scalable human-based coding method. In our coding, we also viewed only single attempts, not looking at preceding or subsequent attempts (as in most prior uses of text replays).

Overfitting is an inherent concern for iterative feature engineering processes; we will discuss in the discussion section why overfitting may be particularly concerning for this paper’s method. Because we wanted to overfit as little as possible, we only looked at text replays of false negatives and false positives. We intentionally did not view text replays of cases of true positives or true negatives. In other words, when we saw a behavioral pattern in false positives or false negatives, we did not double-check whether it was also seen in true positive or true negative cases, with a goal of deriving more features rather than attempting to conduct feature selection by hand by looking at the data (which could increase risk of over-fitting).

Our text replay and qualitative coding processes identified 14 additional features that we then developed software to apply to the dataset. Four of these new features related to scaffold use: **Multiple Uses Of Same Scaffold**, the number of times a student used the same learning support more than once in the same attempt; **Short Scaffold Time**, the number of times a student spent less than five seconds interacting with a scaffold; **Early Scaffold Use**, the number of times that a scaffold use appeared in the first third of actions that a student took in a given attempt; and **Multiple Scaffolds In Attempt**, the number of times that a student used more than one scaffold in the same attempt. Four features related to attempt duration: **Long Attempt Count**, the total number of attempts over three minutes; **Average Last Three Attempt Times**, the average duration of the last three attempts that a student had; **Attempt Time Standard Deviation**, the standard deviation of time across all student attempts so far; and **Previous Attempt Duration**, the duration of the attempt immediately before the current one. Three new features related to machine drawing and use: **Net Objects Drawn**, the number of objects a student drew on the current attempt minus the number of objects a student erased; **Time Spent Drawing**, the total elapsed time between the start and end of a student drawing a machine; and **Unexpected Machine Used**, whether a student drew a machine that was not associated with the knowledge component of the current level. We also created a feature for **Consecutive Nudges**, the number of consecutive times the student clicked on the ball to attempt to move it (cf. [9]), and a feature for **Recently Restarted**, whether the student restarted an attempt within the last 120 seconds. A restart is when a student unsuccessfully solves a level, but retries the same level rather than quitting and going to a new one.

The final re-design to our model, which we called **Quit Flush**, went beyond just creating a new feature. During coding, especially for false positives, we noticed that the model would continue to predict quitting after a quit event when the student did not subsequently quit. A student would begin a new attempt with the model already predicting that the student would quit. Then, some amount of time after the attempt had started, the quit prediction would drop off, and the student would go on to either restart the level or complete it successfully. We hypothesized that this was because the student may have quit in an earlier attempt, and the model had not yet caught up to the student’s new behavioral patterns in a different visit. Therefore, we constructed a separate dataset, which we called the Quit Flush dataset. In this dataset, we reset the values of *all* features following a quit event, starting the model over again from a blank slate whenever a quit was identified.

Following this feature engineering process, we replicated the model fitting steps of the original model exactly. We also fit a series of models where we held out each new feature, to examine the performance gain from adding each feature into the new model.

3. RESULTS

3.1 Original Model vs. Enhanced Model

Our enhanced model, using all 14 newly engineered features (but not including the quit flush), produced an AUC of 0.812 – a gain of almost 0.10, and a 15% improvement over the original model. The enhanced model’s performance is comparable to the best performing models developed by [10], even with the limitation of a relatively simple logistic regression rather than the more sophisticated classification algorithm used in that paper. We will

call this model the “enhanced model” with “enhanced features” in this paper.

3.2 Enhanced Model vs. Quit Flush Model

The quit flush model, using all 14 newly engineered features and resetting all features’ values after a quit, produced an AUC of 0.616 – slightly worse than even the original model. The poor performance of the quit flush model suggests that student quitting events are “sticky”, and that moving between levels does not necessarily indicate that a student starts working productively.

An ROC curve comparison between the AUC of the original model, enhanced model, and quit flush model is given in Figure 2.

Figure 2. Comparison between Original Model AUC, Enhanced Model AUC, and Quit Flush Model AUC.

3.3 Leave One Out Model Results

Following our fitting of the enhanced model and the quit flush model, we then fit subsequent iterations of the enhanced model, holding one feature out each time. The purpose of this analysis was to identify the contribution that each individual feature made to the overall performance of the model.

Table 1. Comparison of feature impact on enhanced model performance.

Feature Name	AUC When Held Out	Delta
Consecutive Nudges	0.742	-0.070
Early Scaffold Used	0.793	-0.019
Previous Attempt Duration	0.812	--
Short Scaffold Use	0.812	--
Attempt Longer Than 3m	0.812	--
Average Last 3 Attempts	0.812	--
Uses of Same Scaffold	0.812	--
Multiple Scaffold Uses	0.812	--
Recent Restart	0.812	--
StD Attempt Duration	0.812	--
Time Drawing Objects	0.812	--

Unusual Object Used	0.812	--
Net Objects Drawn	0.812	--

We found that the performance increase of the enhanced model was driven primarily by just two features – **consecutive nudges**, and **early learning support use**. Student use of consecutive nudges was also found to be associated with student quitting in research by [9] – it is possible that students using nudges repeatedly could indicate that the student is trying to make an ineffective solution work when they cannot figure out a more productive means of solving the level. Further analysis of this behavior, perhaps incorporating qualitative interview data from students during or immediately after gameplay, could contribute to a better understanding of this behavioral pattern. Early use of learning support could either indicate a student who is completely stuck and doesn’t know where to start, or a lack of willingness to put in effort to solve a level, either of which could lead a student to quit.

4. DISCUSSION AND CONCLUSION

In this paper we demonstrate that iterative feature engineering using cases of model mis-prediction, conducting qualitative coding of text replays on instances of false positives and false negatives, can enhance model performance. We found that an “enhanced” model, using features that we developed through this method, performed 15% better than an “original” model on the same dataset. This performance gain came from just two of the 14 features that we iteratively engineered. We have several potential applications for this methodology, and an important caveat to make.

4.1 Applications of Iterative Feature Engineering

Educational data mining has been applied to a wide variety of problems, and we believe that iterative feature engineering may have specific learning contexts where it is more useful. Specifically, this technique relies on having rich, nuanced log data from which specific details of student interaction with the system can be drawn. For relatively simple contexts, such as students working on an online quiz system with very few choices or different components, this method may be more difficult to apply successfully, as there may not be enough variation in behavior for iterative feature engineering to be useful. On the other hand, contexts with rich contextual data may be better suited for this method. This method may be particularly useful for improving prediction models that were already developed using text replays [20, 11, 5, 23], though there is not a principled reason why the method could not be useful even for models initially developed using other methods. In applying iterative feature engineering to models not developed using text replays, it may be relevant to consider whether the behavior can be identified and understood from text replays – some forms of affect, for instance, may be difficult for humans to identify directly from this type of data.

4.2 Using Iterative Feature Engineering to Address Uneven Quality Across Populations

In this work, we applied our iterative feature engineering process to the entire dataset. However, recent papers have found that many EDM models can perform unevenly for different populations of learners, such as rural students versus urban students or non-native speakers versus native speakers (see review

in [3]). We believe that the approach proposed in this paper may be a useful tool for fixing this type of inequity. Training separate models on each sub-population within the full dataset, and conducting qualitative coding on instances of error within these sub-population, could highlight different behavioral patterns seen for individuals in different groups. Population-specific features could then be engineered to equalize the performance of the model across groups of learners.

4.3 Caveat – The Potential for Overfitting

Consider this technique taken to its logical conclusion – monkeys on infinite typewriters, endlessly thresholding and re-thresholding features, defining and re-defining cutoffs, until the billionth permutation of this process produces a model with no error. This model, obviously, would be massively overfit and of next to no use in any broader context, such as on a new class of students. In practice, there are likely not enough educational data monkeys in the world to produce a model with no error. That said, conducting several cycles of iteration on the same dataset does run the risk of overfitting one's feature engineering process, and subsequently the model, to the particulars of the dataset being used. Therefore, this is likely a method best used only limited times over the course of model development. Ultimately, fully-withheld test datasets – or better yet, the collection of new datasets after the fitting process is complete -- should be used in final evaluation of a model (as seen in the trajectory of gaming the system modeling between [19] and [18]). It is not yet known how much iteration of this nature is beneficial, before diminishing returns or overfitting occur. It may be a valuable step for future research to investigate iterating multiple times and observing changes in model performance, identifying the elbow point for improvement. From the perspective of quantitative ethnography, researchers might consider stopping the iterative process when reaching *theoretical saturation*, seeing more data but failing to generate new insights [25].

4.4 Alternative Approaches to Feature Engineering and Text Replays

In this paper, we started with a model with initial features and then refined the model by examining the misclassified cases and deriving new features based on the qualitative interpretations of game play behaviors. However, this is not the only way that an iterative process of feature engineering could be conducted. [26] outline an alternative approach for constructing a theoretical-based and analytics-driven model by grounding analyses in qualitative data and exploring the pattern of data before model construction. Epistemic Network Analysis (ENA) models the co-occurrence of behaviors based on coded qualitative data and unpacks the complexity in the learning process [27]. Used first in epistemic games, other scholars have begun applying ENA techniques to this same problem. For example, [9] adopted ENA to explore why learners quit levels in *Physics Playground*, investigating cognitive processes based on student interaction with the game. Their study identified that students who crystalize their problem-solving strategy at the beginning of gameplay are more likely to quit the levels. This behavior pattern suggests new features to be engineered for the future study of quit model prediction.

4.5 Further Model Development and Future Directions

Poor performance of the quit flush model suggests that a student-level model may be beneficial to predicting quitting. Originally,

our justification for creating the quit flush model was that we observed cases of quitting being predicted at the beginning of an attempt, and we hypothesized that this could be due to the model continuing to predict quitting behavior immediately after a quit event occurs. We anticipated that a quit flush feature would improve overall model performance by addressing these cases; however, the quit flush model performed significantly worse than both the enhanced and original models. Given this difference in performance, it is possible that an enhanced model which uses features aggregated across visits or even sessions of play, could be a more effective predictor than the simple count and duration features that we used in the current work. Previous work on *Physics Playground* has identified the existence of player typologies [30], representing distinct approaches that groups of players employ when playing *Physics Playground*. This work found that students who played *Physics Playground* could be assigned to one of three classes: *achievers*, motivated by in-game rewards such as badges; *explorers*, motivated by the ability to explore the game space, design interesting and unique machines, and push the boundaries of the physics simulation, and *disengaged* players, those players who did not engage with the game to the same degree as their peers. These classes of players could serve as valuable student-level features that inform overall patterns of play. Further work on this topic may also use features aggregated up to each level, as previous work has [10, 13]. While we did not use these features for the current work, because of difficulties in generating these variables at run-time inside the game environment, future work that is focused on using the quit model for analysis entirely outside of the game might benefit from using these various levels of aggregation.

This work has leveraged qualitative analysis in a somewhat different fashion than prior efforts within the EDM community. Qualitative techniques are not new within the fields of educational data mining and learning analytics. Text replays – human review of student behavior to generate labels – have been used for over a decade [2]. Similar work, such as [16] has focused on generating human-readable samples of student-tutor interactions. However, these methods are usually used to generate ground truth labels in order to construct models, or to better understand the relationships that these behaviors have with one another. In this paper, we utilize qualitative coding of student behaviors to develop features that subsequent models can be trained on. By bringing more qualitative understanding and analysis into educational data mining and learning analytics, and synthesizing these approaches with quantitative modeling practices, we can develop models that perform better and are more understandable by the research community.

5. ACKNOWLEDGMENTS

We would like to thank the *Physics Playground* team for their assistance in producing the datasets used.

ABSTRACT

Selecting courses in an open-curriculum education program is a difficult task for students and academic advisors. Course recommendation systems nowadays can be used to reduce the complexity of this task. To control the recommendation error, we argue that course recommendations need to be provided together with *statistical* confidence. The latter can be used for computing a statistically valid set of recommended courses that contains courses a student is likely to take with a probability of at least $1 - \epsilon$ for a user-specified significance level ϵ . For that purpose, we introduce a generic algorithm for course recommendation based on the conformal prediction framework. The algorithm is used for implementing two conformal course recommender systems. Through experimentation, we show that these systems accurately suggest courses to students while maintaining statistically valid sets of courses recommended.

Recommender Systems, Course Recommendation, Conformal Prediction

1. INTRODUCTION

Recommender systems are systems capable of predicting the preferences of users over sets of items [1]. They can be found almost everywhere in the digital space, shaping the choices we make, the products we buy, the books we read, or the movies we watch. The range of applications of recommender systems has been broadened recently to the education domain, especially in higher education [5]. There are systems reported that provide recommendations for academic choices, learning activities, learning resources, and learning collaborations [14].

Among the recommender systems for academic choices, there exists a particular interest in systems that recommend courses [3]. There is a wide range of such systems that differ in the underlying recommendation mechanism, accuracy, type of

recommendations (courses, course sequences, course concentrations), and type of representation. It has been recently recognized that course recommender systems need to be safe [11]; i.e., course recommendations need to be provided with confidence information that will help a student to make a better course selection. There exist different approaches to delivering such confidence information from course preference ranks estimated by the underlying recommendation mechanisms [3, 6, 10, 12] to separate warning modules [11]. The characteristic feature of these approaches is that they are heuristic, and thus they do not provide any theoretical guarantees for the quality of course recommendation.

In this paper, we argue that course recommendations need to be supported with *statistical* confidence. This confidence will allow computing a statistically valid set of recommended courses that contains courses a student is likely to take with a probability of at least $1 - \epsilon$ for a user-specified significance level ϵ . To achieve this, we employ the well-known conformal-prediction framework [4, 15, 16]. We design a generic algorithm for conformal course recommendation capable of computing statistically valid sets of courses for students. The algorithm is used for implementing two conformal course recommender systems that employ a content-based recommendation mechanism. The first system is instance-based, and the second system is an exemplar-based system [13].

The conformal course recommender systems have been implemented for academic advising of University College Maastricht, a Liberal Arts Bachelor study with an open curriculum. In this study, students personalize their program by selecting courses that align with their academic and personal interests. In total, students choose around 40 out of the 160 possible educational modules; i.e., they create a program by selecting one path out of $\binom{160}{40}$ possible. Our recommender systems are tested to facilitate this process. The initial experimental results show that the systems accurately recommend courses while providing statistically valid sets of courses recommended.

The rest of the paper is organized as follows. The related work is provided in Section 2. Section 3 formalizes the task of course recommendation. The course and student topic models used for course recommendation are briefly described in Section 4. Section 5 introduces the generic algorithm for conformal course recommendation and its instantiations: the instance-based and exemplar-based recommender sys-

Zachary Warnes and Evgueni Smirnov "Course Recommender Systems with Statistical Confidence" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 509 - 515

tems. The student-course data is described in Section 6. Section 7 provides the experiments and discussion. Finally, Section 8 concludes the paper.

2. RELATED WORK

Course recommender systems received significant attention since the very first publications [12, 18, 17]. Meanwhile, these systems have become very diverse. Following the main trends in recommender-system research there are different types of course recommender systems: content-based systems [10, 11], collaborative-filtering systems [3], hybrid systems [3, 6], and popularity-based ranking systems [6]. Most of these systems are capable of providing (explicitly/implicitly) confidence information for course recommendations. However, this does not give any guarantee for the quality of course recommendation in a statistical sense.

Confidence-based recommender systems have been proposed based on collaborative filtering. The first system is based on group recommender systems [8], and the second one is based on matrix factorization [7]. Both systems can be directly applied for course recommendations, however, under assumptions typical for collaborative filtering. For example, plenty of data is available; the course order does not matter. In this context, we note that we propose a generic algorithm for conformal course recommendation that is not tailored to the recommendation mechanism: collaborative filtering or content-based filtering. The only requirement to apply this algorithm is to have a function that estimates the typicality of a course w.r.t. other courses taken by a student (see conformity functions in Section 5).

3. RECOMMENDATION TASK WITH CONFIDENCE

Let T be a set of topics t considered in a set C courses c . To indicate the degree of presence of topic t in course $c \in C$ we employ weight $w_{c,t}$. Topic weights $w_{c,t}$ of course $c \in C$ represents a topic model of this course. We assume that the topic models (i.e. topics' weights $w_{c,t}$) are provided initially for all the courses $c \in C$. We describe our approach to derive these models in the next Section.

The courses $c \in C$ are given for a set S of students s . To indicate the degree student $s \in S$ masters topic t we employ weight $w_{s,t}$. Topic weights $w_{s,t}$ of student $s \in S$ represents a topic model of the student w.r.t. courses $c \in C$. Thus, they are computed w.r.t. set C_s of courses student s has taken; i.e. for any topic $t \in T$ we have:

$$w_{s,t} = \frac{\sum_{c \in C_s} w_{c,t}}{|C_s|}, \quad (1)$$

If we assume a specific ordering of the topics $t \in T$, then:

- the topics' weights $w_{c,t}$ for course c form a topic-model vector w_c for c , and
- the topics' weights $w_{s,t}$ for student s form a topic-model vector w_s for s .

The topic-model vectors w_c and w_s "live" in the same space W . Due to the number $|T|$ of all the topics, we employ the

cosine similarity over W . It can be used to compute similarity for any two topic-model vectors that represent courses and students.

The topic-model vectors w_c of all the courses $c \in C$ form the course data set W_C defined as $\{w_c\}_{c \in C}$. Analogously, the topic-model vector w_t of all the students $t \in T$ form the student data set W_S defined as $\{w_t\}_{t \in T}$. In this context, we introduce the recommendation task considered in this paper. Given a course data set W_C , a student data set W_S , and a student $s \in S$ with topic-model vector $w_s \in W_S$, the task is to compute a recommendation set $C_s^\epsilon \subseteq C \setminus C_s$ that contains courses that indeed fit student s with a probability at least $1 - \epsilon$ for a predefined significance level $\epsilon \in [0, 1]$.

4. COURSE AND STUDENT TOPIC MODELING

We employed the topic-modeling approach proposed in [11]. The set T of topics t was identified from the course descriptions using the Latent Dirichlet Allocation (LDA) generative model [2]. Each topic $t \in T$ is given by a probability distribution over the vocabulary derived from all the descriptions. Thus, each course $c \in C$ is represented by topics t , which words are present in the description of that course. Student topic models are derived based on the topics courses using formula (1).

5. CONFORMAL COURSE RECOMMENDATION

This section introduces a conformal course recommendation. First, we present a conformal test for course inclusion and a generic algorithm for conformal course recommender systems. Then we provide two instantiations of this algorithm.

5.1 Generic Conformal Course Recommender

Consider a particular student $s \in S$ with her set C_s of courses. We assume that student s is represented by a probability distribution P_s ; i.e. P_s has generated the course set C_s for s . Thus, to decide whether to recommend a new course $c \notin C_s$ for student s , we perform a statistical test of the null hypothesis that the set $C_s \cup \{c\}$ is generated by the student distribution P_s under the exchangeability assumption [15]¹.

We implement the statistical test according to the conformal-prediction framework [15]. It makes use of course conformity scores. The conformity score α_c of a course c is defined as a score that indicates how typical c in set $C_s \cup \{c\}$. The conformity score α_c is computed by a course conformity function A . The latter is a mapping from $2^C \times C$ to $\mathbb{R} \cup \{+\infty\}$; i.e. it returns for any course set C_s and any course c a score α_c that indicates how typical is course c for the courses in $C_s \cup \{c\}$. Depending on the implementation of the conformity function for the course and student topic models, we can have recommender systems based on content/collaborative filtering (See the next section).

The conformity score α_c of a new course c is used as a test statistic for the null hypothesis that the set $C_s \cup \{c\}$ is generated by the student distribution P_s according to the

¹We note that the exchangeability assumption is weaker than the well-know i.i.d. assumption.

exchangeability assumption. The p -value p_c for the null hypothesis, is calculated as the fraction of the courses in $C_s \cup \{c\}$ associated with conformity scores that are equal to or smaller than α_c . The larger the value of p_c , the more likely it is to observe the value of α_c under the null hypothesis, and the more confidence we have in course c . If we set a course significance level ϵ_c (probability of the error) in range of $[0, 1]$, then the statistical test will accept the null hypothesis if $p_c > \epsilon_c$ and course c will be recommended.

If we perform the statistical test from above for student $s \in S$ over all n courses from set $C \setminus C_s$ (that s has not taken), then we can compute a recommended set of courses. We summarize this process in Algorithm 1 given below. It presents a generic conformal course recommender algorithm. Given a course significance level $\epsilon_c \in [0, 1]$ and set C_s of m courses taken by student s , the algorithm computes set $C_s^\epsilon \subseteq C \setminus C_s$ of recommended courses for student s on the chosen significance level ϵ . To decide whether to include course $c_i \in C \setminus C_s$ in set C_s^ϵ the algorithm computes the conformity score α_{c_j} for each course $c_j \in C_s \cup \{c_i\}$ using the nonconformity function A (step 4). The conformity scores α_{c_j} are used for computing the p -value p_{c_i} of course c_i (step 6). Once p_{c_i} has been obtained, course c_i is added to the set C_s^ϵ of recommended courses if $p_{c_i} > \epsilon_c$ (step 7). This process is repeated for every course $c_i \in C \setminus C_s$.

We note that the generic conformal course recommender algorithm computes valid recommendation sets C_s^ϵ for a significance level ϵ that usually is bigger than the course significance level ϵ_c (used in Algorithm 1). To explain this phenomena we follow the approach proposed in [9]. W.l.o.g. assume that the set $C \setminus C_s$ is the same for all the students $s \in S$. Let e_{c_i} be a random error variable for a course c_i from the n courses in $C \setminus C_s$. The variable e_{c_i} equals 1 if course c_i does not fit student s ; and 0, otherwise. Assume that we set the course significance level ϵ_c so that $p(e_{c_1} = 1) < \epsilon_c, p(e_{c_2} = 1) < \epsilon_c, \dots, p(e_{c_n} = 1) < \epsilon_c$. This implies that the expected number of courses incorrectly recommended, $e_{c_1} + e_{c_2} + \dots + e_{c_n}$, is bounded by $n\epsilon_c$; i.e. $\mathbf{E}[\sum_{c_i \in C \setminus C_s} e_{c_i}] \leq n\epsilon_c$. If we know number t of courses from $C \setminus C_s$ that fit student s in advance, then:

$$\frac{1}{t} \mathbf{E}[\sum_{c_i \in C \setminus C_s} e_{c_i}] \leq \frac{n}{t} \epsilon_c. \quad (2)$$

We note that $\frac{1}{t} \mathbf{E}[\sum_{c_i \in C \setminus C_s} e_{c_i}]$ is the expected error and $\frac{n}{t} \epsilon_c$ is a significance level ϵ for which validity of recommendation sets C_s^ϵ can be established. This implies:

$$\epsilon_c = \frac{t}{n} \epsilon \quad (3)$$

Thus, to guarantee valid recommendation sets $C_s^\epsilon \subseteq C \setminus C_s$ that contains courses that fit students with a probability at least $1 - \epsilon$ we need to set the course significance level ϵ_c according to formula (3) when we initialize the generic conformal course recommender algorithm from Algorithm 1.

Algorithm 1 Generic Conformal Course Recommender

Input: Course significance level ϵ_c ,
Set C_s of m courses taken by student s .
Output: Set C_s^ϵ of recommended courses for student s .

- 1: Set course set C_s^ϵ equal to \emptyset .
- 2: **for each** course $c_i \in C \setminus C_s$ **do**
- 3: **for each** course $c_j \in C_s \cup \{c_i\}$ **do**
- 4: Set conformity score α_{c_j} of course c_j equal to $A(C_s \cup \{c_i\}, c_j)$.
- 5: **end for**
- 6: Set p_{c_i} equal to $\frac{\#\{c_j \in C_s \cup \{c_i\} \mid \alpha_{c_j} \leq \alpha_{c_i}\}}{m+1}$.
- 7: Add course c_i to C_s^ϵ if $p_{c_i} > \epsilon_c$.
- 8: **end for**
- 9: Output set C_s^ϵ of recommended courses for student s .

To establish the validity of sets C_s^ϵ of recommended courses, we adapt the error metric from [9, 19]. Assume that for student $s \in S$, we have a test set of courses, and we know that within this set, there is a true set C_s^t of courses that student s will take. We define the individual error e_s for student $s \in S$ as the proportion of the courses in the true set C_s^t that are not recommended, i.e.

$$e_s = \frac{|C_s^t \setminus (C_s^\epsilon \cap C_s^t)|}{|C_s^t|}.$$

In this context, the error e of a conformal course recommender is defined as the averaged error e over all the students $s \in S$:

$$e = \frac{\sum_{s \in S} e_s}{|S|}.$$

We note that the individual error e_s corresponds to the expected error $\frac{1}{|C_s^t|} \mathbf{E}[\sum_{c_i \in C \setminus C_s} e_{c_i}]$. Thus, to show experimentally that a conformal course recommender is valid for any significance level ϵ in $[0, 1]$, we have to show that the error e is less than or equal to ϵ .

The validity of a conformal course recommender can be trivially achieved if the recommender outputs all the possible courses from set $C \setminus C_s$. Thus, we need to estimate the informational efficiency of the recommender. For this purpose we employ the size SR of the recommended set C_s^ϵ of courses averaged over all the students:

$$SR = \frac{\sum_{s \in S} |C_s^\epsilon|}{|S|}.$$

5.2 Content-based Conformal Course Recommender Systems

The generic conformal course recommender algorithm can be instantiated if we specify the course conformity function A . This function can be done using different recommender mechanisms, e.g., collaborative filtering or content-based filtering. In this paper, we assume the existence of topic model

vectors of courses and students that fit the content-based filtering scenario (see Section 3). That is why we propose conformity functions for two content-based conformal course recommender systems specified below.

The first system is an instance-based conformal course recommender system (ICCRS). Any student $s \in S$ is represented by a set of topic-model vectors (instances) w_c of the courses $c \in C_s$ she has taken. In this context the course conformity function A outputs for any course $c \in C$ and course set C_s of student $s \in S$ an averaged similarity of c with courses in C_s ; i.e. $\frac{1}{|C_s \setminus \{c\}|} \sum_{c' \in C_s \setminus \{c\}} \cos(w_c, w_{c'})$ where \cos is the cosine similarity.

The second system is an exemplar-based conformal course recommender system (ECCRS). It employs topic-model vector w_s (exemplar) of student $s \in S$ computed using formula (1). In this context the course conformity function A outputs for any course $c \in C$ and course set C_s of student $s \in S$ a value equal to $\cos(w_c, w_s)$, where topic-model vector w_s of student $s \in S$ is based on the courses in $C_s \setminus \{c\}$ and \cos is the cosine similarity.

The computational complexity of ECCRS is higher than that of ICCRS since, for any student, we need to recompute her topic-model vectors w_s by excluding courses one by one. However, ECCRS has better explanation capabilities. The topic-model vector w_s of student s represents the current levels of topic mastering, and the topic-model vector w_c , of course, c represents the topics covered in the course. Thus, the cosine match can explain why the course has been selected/rejected.

6. STUDENT-COURSE DATA

ICCRS and ECCRS have been implemented as course recommender systems for University College Maastricht. The college has provided course enrollment data from 2008 to 2017. This data includes course and student identifiers, grades for each course, details regarding course assessment, ECT credits, and course descriptions. The course descriptions facilitate the construction of topic values for both the student model and the course model. The calculation of topic values is with LDA, and an optimal number of topics is determined through maximum likelihood estimation. This optimization results in sixty-five topic areas representing the course catalog [11]. We remove modules without descriptions from consideration. In total, 143 courses and 2422 students enrolled in at least one course remain.

The rates of course enrollments vary widely between each course. Registration in the majority of courses offered occurs only a few times over the entire period, see in Figure 1. The modules provided are updated each year, reflecting the changes to the course catalog via dropping courses and course code changes. Several introductory courses, required courses, and projects make up a significant portion of all enrollments. Most students at UCM need eighteen periods to complete their education. Nevertheless, some students enroll in over twenty periods. See Figure 2. Each recommender system focuses on a subset of twelve periods representing two years at UCM. The subset is refined further by selecting only students starting in the fall intake semester. These restrictions increase the standardization of students

for our systems, and balance for the diversity of enrollment patterns present in an open-course curriculum. Our recommender systems use the remaining 1018 students that fall within these boundaries.

Figure 1: Total Number of Course Enrollments

Figure 2: Total Number of Student Enrollments per Period

University College Maastricht offers a project-based curriculum. Two of the six periods each year are for student projects (periods three and six). The choice of courses within project periods is restricted. See Figure 3. Excluding these project periods, the average courses offered each period is 31 with a maximum of 44 courses. Figure 3 shows the variation in course offerings throughout the UCM data available. This variation is taken into account by our systems, and we omit these project periods from calibration. Course recommendations include only those courses offered in the target period. Therefore, recommending the maximum number of courses for a period results in a 0% error.

Figure 3: Courses Offered in Each Academic Period

7. EXPERIMENTS

This section presents experiments of ICCRS and ECCRS on the student-course data provided by University College Maastricht (see Section 6). First, an experimental setup is given, followed by results and discussion.

7.1 Setup

We validate ICCRS and ECCRS on the student-course data in the order of study periods. Assume that we have M number of periods P_1, \dots, P_M in which a student studies towards her degree (for our data M is equal to 18). We denote by $C_s(P_m) \subseteq C_s$ the set of courses that student s has taken in period P_m for $m < M$. Given new period P_{m+1} together with the set $\cup_{m=1}^M C_s(P_m)$ of courses student s has taken before that period, we test our recommender systems by checking whether the recommended sets C_s^ϵ of courses for P_{m+1} includes the courses $C_s(P_{m+1})$ that student s indeed has taken in P_{m+1} .

Figure 4: Prediction Process for Period P_{m+1}

We validate ICCRS and ECCRS using data from students in their second year of study. This choice is due to the fact the number of p -values possible is related to the number of courses a student has taken (see line 6 of the generic conformal course recommender in Algorithm 1). For example, a student with only three courses taken in period P_1 of year one can only have p values from the set $\{\frac{1}{4}, \frac{1}{2}, \frac{3}{4}, 1\}$ for any new course in period P_2 .

For the validation process, we estimate the average error of e , and the average size of SR of the recommended sets C_s^ϵ of courses. We then use these statistics to study ICCRS and ECCRS as conformal predictors and as recommender systems.

In the first study, when we investigate ICCRS and ECCRS as conformal predictors, we are interested in establishing the validity and informational efficiency of the systems (check Sub-section 5.1). In the second study, when we investigate ICCRS and ECCRS as recommender systems, we are interested in estimating the error of the systems over the periods when we employ the recommended sets C_s^ϵ on a given course significance level ϵ . In our experiments, we use course significance levels ϵ of 0.05 and 0.1.

7.2 Results and Discussion

Figures 6 and 7 present the error plots and size plots of the recommended sets C_s^ϵ of ICCRS and ECCRS, respectively, for course significance level ϵ_c ². The error curves are very close to the diagonal $(0, 0) - (1, 1)$, which means the error is close to the course significance level ϵ_c . For ICCRS, the

²We use the course significance level ϵ_c instead of the significance level ϵ for the predicted course sets since the range of ϵ is very restricted according to formula (3); e.g. $[0, 0.025]$ for 40 possible courses in a study period.

error is bounded mainly from above. For ECCRS, the error is bounded mainly from below. This bounding indicates that the systems are valid given sufficient information, especially ICCRS, which is conservatively valid [15].

The conservative validity of ICCRS explains why the averaged size SR of the recommended sets $C_s^{\epsilon_c}$ is higher than that of ECCRS. Thus, we may conclude that the informational efficiency of ECCRS is better in our experiments.

Figure 5: Period errors of ICCRS and ECCRS on course significance level ϵ_c of 0.05 and 0.1

Figure 5 presents the error of ICCRS and ECCRS when recommended sets C_s^ϵ on course significance levels ϵ_c of 0.05 and 0.1 are used. The systems are applied over periods of P_1, P_2, P_3, P_4, P_5 , and P_6 of the second year of the UCM students. The results show that:

- ICCRS and ECCRS produce accurate recommended sets of courses with an acceptable error.
- ICCRS is more accurate than ECCRS. This difference can be explained by the fact that ICCRS is more conservatively valid.
- the course significance level ϵ_c plays a substantial role: for 0.05, the error of recommended sets C_s^ϵ is much lower. However, this comes with a price: the size of the recommended sets is bigger when epsilon is lower.

8. CONCLUSION

This paper shows that safe course selection can be obtained if recommendations are supported with statistical confidence. The statistical confidence can be used for computing a statistically valid set of recommended courses that contains courses a student is likely to take with a probability of at least $1 - \epsilon$ for a user-defined significance level ϵ .

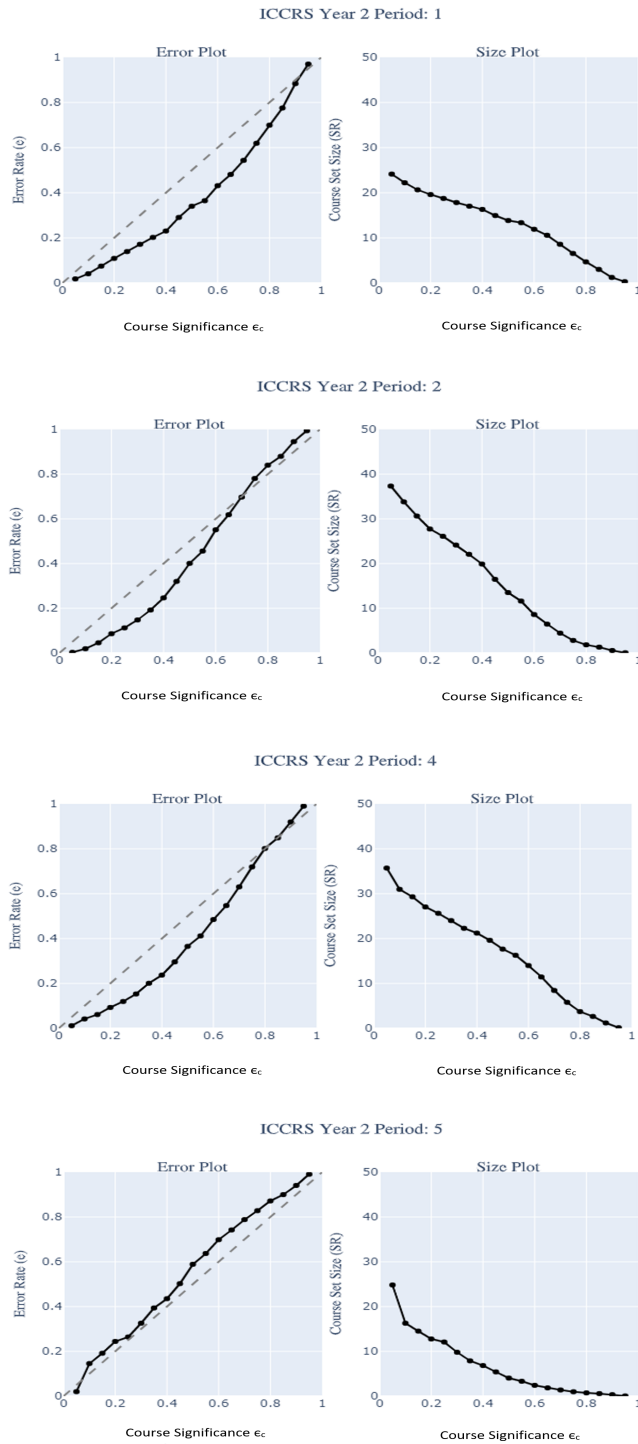

Figure 6: ICCRS - Calibration and Course Set Sizes

Figure 7: ECCRS - Calibration and Course Set Sizes

We have developed a generic conformal course recommender algorithm that outputs recommendations supported by statistical confidence. The algorithm has been instantiated in the form of two confidence-based course recommendation systems. The systems are essentially content-based: the first is an instance-based recommender system with rela-

tively high accuracy. The second system is an exemplar-based system with a lower accuracy but with better explanatory capabilities. The experiments showed that both systems accurately suggest courses to students while providing statistically valid sets of courses recommended.

ABSTRACT

Peer assessment adds value when students provide “helpful” feedback to their peers. But, this begs the question of how we determine “helpfulness.” One important aspect is whether the review detects problems in the submitted work. To recognize problem detection, researchers have employed NLP and machine-learning text classification methods. Past studies have used datasets that were narrowly focused on a small number of classes in specific academic fields. This paper reports on how well models trained on one dataset or field perform on data from classes that are unlike the classes whose data they have been trained on. Specifically we took a model developed with data from a computer science class with several programming assignments, and tried to transfer it onto an education class focused more on writing research papers. We have attempted to perform such a task on a few models including logistic regression classifier, random forest classifier, multinomial naive bayes classifier and support vector machine. We made several attempts to raise the accuracy of classification, including lemmatizing to deduct variation in data input, and active learning strategies.

1. INTRODUCTION

The term “peer assessment” means students reviewing each other’s work. The practice has been widely used for at least fifty years. It began as a face-to-face process, with students exchanging their papers. For the last twenty-five years or so, peer assessment has also been performed using online applications. Peer assessment has many advantages. From a pedagogical point of view, the greatest advantage is that it helps students understand the requirements for the assignment, and see how their work measures up to their peers [1, 2, 3, 4, 5]. This helps them to improve their own work product. From an operational standpoint, peer assessment is scalable—no matter how many students are in the course, students’ work does not want for personal attention. This makes peer assessment especially useful for MOOCs, where

it is frequently to provide feedback and to assign grades.

Student work on a MOOC can be graded in different ways. If objective questions are posed, such as multiple-choice and true/false questions, they can be automatically graded by software that checks whether answers match the key, while for subjective issues such as coding projects and essays, it becomes a bigger challenge. These platforms often utilize quantitative methods such as averaging reviewer scores on multiple sections of peer assessment related to the course assignment.

Current peer grading approaches are based on the numerical scores assigned to rubric items by each reviewer. Rarely do they utilize another very important piece of information: the justification given by reviewers for the grades they’re giving.

Fundamentally, the quality of a review is related to whether it identifies ways for the author to improve the work. Thus, it is important for the review to point out shortcomings or problems in the existing work. Other researchers [6] have done preliminary work in this area. They have looked at approaches to detecting suggestions [7], for the reason that suggestions help students act on improving the work they have done. Other work involves recognizing problem statements. A problem statement helps people realize the shortcomings in their work, and pointing out a problem does not require as much thinking as knowing what is wrong and coming up with a solution to correct the problem as making a suggestion does. In the context of peer review, if we could tell whether a comment contains one of these features (suggestion or problem statement), we could compare a reviewer’s work with other reviewers’ and urge him/her to add more to the review if his/her review lacks these features significantly. In order to accomplish it, a means of automatically detecting these features needs to be devised.

We have built text classifiers that can recognize whether a comment contains a problem statement; however there’s a drawback. As researchers know, text classifiers are very domain specific, that is if a classifier is trained on one specific domain, it will probably not perform well when used on another domain [8]. When MOOCs offer classes in multiple fields, the peer reviews in each class will have different language features. Useful sentiment features such as problem statements would not be the same in different classes. Traditionally, there would be multiple classifiers trained on each

Yunkai Xiao, Gabriel Zingle, Qinjin Jia, Shoaib Akbar, Song Yang, Muyao Dong, Li Qi and Edward Gehringer “Problem detection in peer assessments between subjects by effective transfer learning and active learning” In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 516 - 523

one of the domains to achieve optimal performance. An issue with this approach is that there needs to be enough labeled data from each of these domains, which in a lot of cases is hard to achieve. Labeling is becoming one of the most expensive steps in machine learning, both from the perspective of time and of money [9]. However, there are a number of ways to work around this problem, if not completely mitigate it.

Researchers have demonstrated that traditional machine learning and deep learning technologies are useful for problem detection in peer review in the computer science field [10]. The researchers aim to generalize the problem detection function to different subjects. There are two potential methods for quickly building a model in a target domain and avoiding much of the time-consuming and expensive data labeling efforts. Such methods include transfer learning and active learning. With these two approaches, problem detection could be transferred quickly to a new field and at a reduced cost.

The first approach is to leverage transfer learning to transfer “knowledge” learned from the problem detection task in the computer science field to the other field. This process can use model insights gained from other datasets to expedite the construction of a new model while including only a small amount of labeled data in the target domain. In our case, we trained a problem detection classifier from data generated in a computer science class. One of the research questions we aim to discuss is leveraging transfer learning to effectively preserve the performance of the model when it is applied to other classes.

The second method is to utilize active learning to label abundant data and then apply machine learning algorithms or train deep neural network models on this automatically labeled data. This method is detailed in the implementations subsection of the experiment section of this paper.

2. LITERATURE REVIEW

2.1 Problem Detection

There have been plenty of attempts to apply natural language processing (NLP) techniques and machine-learning (ML) algorithms on automating various aspects of review assessment. Brun and Hagege [11] leveraged NLP techniques to identify suggestions in review text. Zingle et al [7] attempted to use different ML and Deep learning algorithms to determine whether a review text contains suggestions. Nguyen et al. [12] used logistic regression to train a model that predicted whether a review comment contained a problem solution. They provided this information to the reviewer before the review was submitted, in order to encourage the reviewer to suggest solutions for problems in the work.

However, most of the current research related to applying NLP and ML on peer review is limited to one subject or ones filled with enough labeled data. For example, research from Zingle et al. [7] collected student annotated peer reviews from a graduate level computer science course and used this labeled data to train models for detecting suggestions in the course. The study by the Brun and Hagege [11] did similarly with abundant manually annotated customer reviews. To the best of our knowledge, there are no pub-

lished papers that address the issue of how to apply NLP and ML on peer reviews in a field without abundant labeled data. This paper is based on previous research about detecting problem statements in peer assessments [10]. This paper focuses on detecting problem statements in a field without abundant labeled reviews by utilizing transfer learning and active learning.

2.2 Transfer Learning

In most traditional machine learning algorithms, an essential hypothesis is that the training data and test data must be in the same feature space and have the same distribution [13, 14]. If the feature space or latent distribution changes, sufficient labeled data from the new domain will be needed and the statistical model must be rebuilt from scratch. This approach can be time-consuming and expensive in many real-world applications like text classification and thus limits its development [15]. The peer-review comments from the computer science field and the peer-review comments from other subjects might be in the same feature space but in different distribution, where plenty of peer-review comments from each field must be labeled and a learner must be reconstructed from scratch for each subject.

In contrast, transfer Learning, which is fundamentally motivated from a discussion in a NIPS-95 workshop [16], relaxes the hypothesis that the training data must be in the same feature space and identically distributed with the test data [13, 14]. The basic idea of transfer learning is to transfer “knowledge” learned from source tasks to different but related target tasks. This is to combat against the problem of an insufficiently large labeled training dataset and to improve the learning of the target task by reducing the labeling cost. In this case, only a small quantity of labeled data in the target domain is required. Negative transfer may occur, but a successful “transfer” would greatly improve the performance and reduce the cost of learning for the target task by avoiding much time-consuming and expensive data labeling efforts.

Pan and Yang [13] summarized various transfer learning settings and categorized transfer learning under three sub-settings. These include inductive transfer learning, transductive transfer learning, and unsupervised transfer learning, based on different situations between the source and target domains and task. This paper is under the inductive transfer learning setting, which has different, yet related source and target domain tasks, where a sufficient quantity of labeled data is only required in the source domain. There are five main approaches for conducting the inductive transfer learning from literature. These approaches are instance-based transfer learning [17, 18], feature-representation transfer [19, 20], parameter-transfer [21, 22], relational-knowledge-transfer problem [23, 24], and Hybrid-based (instance and parameter) transfer learning [25, 26].

The parameter-transfer approach mentioned above is a simple but effective method for transferring “knowledge” by sharing parameters. Assumption of the approach is that some parameters are shared by source tasks and target tasks [13]. The “knowledge” is encoded into and transferred across tasks by those shared parameters.

2.3 Active Learning

Active Learning is a significant subfield of machine learning and a helpful technique in many real-world applications where there is abundant unlabeled data, but where labels are difficult, time-consuming, or expensive to acquire [27]. Active learning algorithms are allowed to interactively query a human annotator called teacher or oracle to label the new data point chosen by a predefined strategy and usually perform better with less labeled training data. There are three main settings in which the learner may be able to query. These settings are membership query synthesis proposed by Angluin [28], stream-based selective sampling proposed by Cohn et al. [29] and pool-based active learning proposed by Lewis and Gale [30].

The most common active learning scenario is the pool-based active learning setting, which assumes that there is a smaller set of labeled data and a large pool of unlabeled instances. The key hypothesis of pool-based active learning is that the learning algorithm would perform better with less training if the algorithm could determine which instances in the pool are the most informative and is allowed to ask queries based on a certain query strategy. This would be in the form of unlabeled instances that are to be labeled by an oracle (e.g. a human annotator) [27, 30]. Hoi and et al. [30] investigated the pool-based scenario on large-scale text classification and first demonstrated the feasibility of batch mode pool-based setting active learning on the text categorization problem.

Under each active learning scenario, there have been a number of query strategies proposed for evaluating the informativeness of unlabeled instances. We evaluated the most common query strategies, uncertainty sampling published by Lewis and Gale [30]. The uncertainty sampling strategy selects the instance in the pool about which model is least certain on how to label observations according to an uncertainty measure like entropy.

In contrast to active learning, traditional passive learning would use a random sampling strategy to select instances from a large pool of unlabeled instances. This strategy generally underperforms compared with uncertainty sampling strategy thus is not adopted here.

3. EXPERIMENT

3.1 Data

To train the problem statement classifier, we used a dataset pulled from the Expertiza system. Expertiza is a web based education platform instructors can use to distribute homework assignments and team projects. The key feature of this platform comes in later stages once students submit their work, where they assess the work product of other students by giving a numeric score as well as a comment to justify their decision. For team assignments, students would assess work done by other teams, as well as the contributions of their teammates.

In some of the classes, students are asked to annotate the comments they received with an incentive of extra credit with a “yes” or “no” on given metrics. For example, some metrics that the students label for include “Does the comment contain a problem statement?”, “Does the comment offers a suggestion?”, or “Was the comment localized to a

particular place in the work?”. This is a valuable source of annotated data for our research, as students should be experts at annotating feedback on their own work. However, many times more steps are required to improve the quality of this data. On observing the annotations, we found a number of problems. Sometimes students would rush through the annotation with the goal of getting extra credit with minimal effort, leaving a trail of yes’s or no’s without actually reading the comments. Other times fatigue may set in while annotating a large number of comments, resulting in the accuracy of labels gradually dropping towards the end of the annotation process. To resolve this issue, the course staff and the research team checks labels applied by the students through random sampling of the students’ annotations. If it appeared that a student was not taking adequate care, that student’s annotations would be removed from the dataset.

We extracted data from computer science class projects. Since every member of the team is involved in annotating reviews they received for team projects, we were able to calculate inter rater reliability using Krippendorff’s alpha, which was relatively low at a value of 0.696. To improve the accuracy of our model, we decided to only take those data with consensus among all annotators, by removing those with any conflicted labels, which decreased the size of our dataset by 4649, resulting in an improved Krippendorff’s alpha of 1. We then further altered the dataset by downsampling the majority class by 313 observations to ensure a balanced proportion of classes.

To prove that language features, specifically for problem statements in this particular dataset could be transferred, we run a test on three other datasets. The first composes Hotel product reviews, the second Amazon reviews, and the third a small dataset from a university level education class. The Hotel and Amazon datasets were found on the website Kaggle, which states that the data originated from the website Datafiniti. Two useful columns from the original datasets included a review score from the original 1 to 5 scale, with 1 being very bad to 5 being very good, and a column with the actual review text. From inspecting the data, we found that reviews with low ratings mentioned problems regarding the respective hotels or amazon products they were reviewing, while there was no mention of a problem in well rated reviews. Based on this information, we kept all the reviews with a rating of 1 or 2 and relabeled them all to the value 1 to represent that these reviews mentioned a problem. We then kept an equal quantity of positive reviews, all labeled 5, and relabeled these to the value 0 to represent that these reviews did not mention a problem.

The target domain dataset that we’re primarily trying to transfer is generated from the education class, which had been taught using the Expertiza system. The nature of assignments in this particular class involves much more writing in terms of research papers as compared with the project based assignment in the computer science class. Students in this class are not asked to annotate the feedback reviews they’ve received, thus creating an issue in terms of a lack of labeled data. Different members of the research team did some manual inspection and annotation on small subsets of this data, then removed those data entries with conflicting labels to reach a complete consensus. This dataset was man-

ually labeled by our research team as either 1 mentioning a problem, or 0 not mentioning a problem.

We started by preprocessing the text in all four of the datasets. Specifically, we removed all punctuation aside from sentence ending period marks. We then removed all special characters and numbers. We removed URL links and converted the text to lowercase. Afterwards, we decided to balance the datasets using downsampling in terms of class proportion for observations mentioning and not mentioning a problem. This helps with models, particularly Naive Bayes, to prevent overpredicting a class based on the proportion of training data of a certain class instead of the input features. However, we did not balance the Education dataset since it was not being used to train the models and due to its small size. The total number of observations in the Expertiza, Hotel, Amazon, and Education datasets were 18354, 4460, 2442, and 172 (122 labeled 0 and 50 labeled 1) respectively.

Additionally, we have attempted to apply lemmatization and stopword removal to gauge its impact on model performance. The intuition of this is with lemmatization, we would reduce the variation of data embedding, helping the models to focus on important features to achieve better results.

3.2 Models

Before we could transfer knowledge into models that work in the target domain, some machine learning from the source domain is required. For this task, we pick four models including the Random Forest classifier, multinomial naïve Bayes classifier, support vector machine, and logistic regression classifier. Each classifier used the same 90-10% train-test split with hyper parameters tuned using 5-fold cross-validation.

Leveraging the power of the Scikit-learn package, we were able to build a data pipeline for this task [31]. Cleaned data was funneled into a count vectorizer, then weight transformed with a TF-IDF transformer, before being used by the classifiers.

The logistic regression classifier uses a regression equation to produce discrete binary outputs through a sigmoid function. It learns the coefficients of each input feature through the fitting process just like in linear regression.

The random forest classifier uses an ensemble approach that fits multiple decision trees, then uses averaging to improve the accuracy of predictions as well as to avoid overfitting. The loss criterion to choose from includes gini and entropy.

The multinomial naïve Bayes classifier is a special instance of a naïve Bayes classifier that follows a multinomial distribution for each feature $p(f_i|c)$. The naïve Bayes model assumes that each of the features it uses for classification are independent of one another.

The support vector machine classifier works by establishing a decision boundary as well as a positive plane and a negative plane between classes. Anything in the positive plane is considered to have the characteristic under study. In our experiment, this is the presence of a problem in a reviewer's comment.

We have also attempted doing the same task with a neural-network based model. One popular network structure in natural language processing is the Long Short Term Memory (LSTM) network. The LSTM takes the cleaned dataset as input, then using GloVe [32] embedding as a feature extractor before feeding them into a stacked LSTM and dense layers.

LSTM is a variation of Recurrent Neural Network (RNN), with the modification of adding the functionality of forgetting information when new information is fed into the network. This particular network leverages existing advantages of memorizing information through timesteps, and in the meantime uses four gates to input, forget, update, and output information.

3.3 Implementations

To validate our ideas on if detecting problem statements could be transferred, we did some initial experiments by training models on one dataset and then test on another. Results of these experiments could be found in the following section of the paper, where we did observe signs of knowledge being transferred and proceeded to the next stage on improving model accuracy on new domains.

Apart from transferring existing knowledge from other domains, the other way to diminish the impact of lacking annotated data is active learning. Active learning helps researchers to lessen the effort annotation by selecting a subset of high value data to annotate. Different active learning strategies may generate different subsets of data, but the essence of doing so is that it would pick data that can bring more knowledge to the models compared with other data points.

During the active learning phase, we attempted applying uncertainty sampling strategy to actively learn the more important groups of data-points listed by each model respectively. Unlabeled data from the education class dataset is exposed to all four models, and they would go through predicting whether a problem statement is present in a comment, generating labels of 1's and 0's as well as corresponding confidence scores. Using the score, we could retain four subsets of data points of which the models' confident scores are between 49% and 51%.

Two researchers then annotate over 100 of these data-points per subset, then remove conflicted entries, leaving 100 labeled data-points which each of these models are "curious" about. These observations are then appended to the computer science dataset which we originally trained the models with. Finally, the four models were re-trained separately.

4. RESULTS

In Tables 1, 2, 3, and 4 the rows represent the dataset that was used to train the model. The columns represent the dataset that was tested on by the model. In the cases marked by the diagonal in the tables, we trained the models using 90% of the dataset and tested on the remaining 10%. The order of the sets of three values within each represent the results without any further text preprocessing, lemmatization, and stopword removal respectively.

Hotel	0.74 / 0.74 / 0.59	0.91 / 0.90 / 0.92	0.73 / 0.74 / 0.73	0.61 / 0.63 / 0.60
Amazon	0.58 / 0.54 / 0.43	0.73 / 0.75 / 0.72	0.91 / 0.93 / 0.91	0.62 / 0.55 / 0.50

When models are trained on one dataset and tested on another dataset without any prior knowledge for the target domain, we could expect some drop in performance. As we tested each model's performance on different datasets, we validated this claim and found that the degradation of model performance is closely related to how much domains differ from each other.

For example, when we initially tested if something constituted a problem statement that was learned from the computer science could be transferred to other domains, we found that despite a drop of 0.2 - 0.3 in F1 score, each model did receive a F1 score larger than 0.6 for most of the runs, which is better than the random guessing average of 50%. This is a sign of positive transferring of knowledge, thus proving our idea could work.

Apart from the naive Bayes classifier, we received good results when testing on the Education dataset. This could be caused by the nature of reviews towards computer science sharing more similarities with the education dataset since they are both done by students towards their peers, unlike the other two. Apart from that, we found the knowledge transferring to the Amazon dataset constantly outperforming knowledge transferring to the Hotel dataset. When closely observing the content of the Amazon dataset, we found it is focused on reviewing electronic devices such as Amazon Kindle and Kindle fire. The nature of such projects do share some similarity with reviewing an application built by a computer science student, and as expected we could find knowledge transferred better from a computer science class to Amazon reviews compared with those from the Hotel dataset. All of the findings above can be found in Tables 1, 2, 3, and 4. Unsurprisingly, when we compare transferring knowledge between different domains through datasets that we have acquired, it can also be found that transferring works the best between the two commercial review datasets, being Amazon and Hotel, due to their nature being customer rather than peer reviews.

We analyzed the most important features most models used for prediction by examining feature coefficients from these models. The results of this examination also aligned with our observations. Within the top 20 positive and negative coefficients, we found 5 pairs of shared features between the computer science dataset and Amazon dataset. We also found 6 pairs between the computer science dataset and

Hotel dataset. Furthermore, there were 7 pairs of shared features between the Amazon dataset and Hotel dataset.

The models resulted in similar performances with and without the use of lemmatization for training and testing on the same dataset. Lemmatization did increase the accuracy when models were trained on the Hotel dataset and tested on the Amazon dataset, and vice versa. However, stopword removal led to a significant decrease in classifier performance in all cases except for when the models were trained and tested on the same dataset for the Hotel and Amazon dataset, in which case the performance was around the same.

The logistic regression classifier and support vector machine led to the best results when training and testing on the same dataset, with the exception of multinomial naive bayes when using the Hotel dataset. Otherwise, the multinomial naive bayes classifier performed the worst, particularly when attempting to predict observations found in the Education dataset.

When tested and trained on the same dataset, the models performed well with f1-scores ranging from mid 80s to mid 90s.

To bring up the accuracy when we transfer a model onto another domain, we did some active learning attempts. By using the uncertainty sampling strategy, each of the four models were exposed to the unlabeled education dataset, then the top hundred data points denoted unsure by each model is extracted. Each of these data points had a confidence between 49% and 51%, and were presented to an oracle (human annotator) for labeling. After removing conflicting labels, these subsets of data were appended to the original computer science dataset individually based on which model mentioned the uncertainty, then used to retrain each model respectively.

We found that with a very small carefully picked set of data, we could regain a considerable amount of accuracy after transferring a model onto a new domain. As could be seen in Figure 1, which details the affects of adding the target domain data from active learning to the computer science dataset, all models gained accuracy with Naive Bayes benefiting the most from this process.

Table 3: F1 Score Naive Bayes

TrainTest	Computer Science	Hotel	Amazon	Education

Hotel	0.66 / 0.66 / 0.56	0.93 / 0.94 / 0.94	0.83 / 0.85 / 0.80	0.65 / 0.62 / 0.61
Amazon	0.63 / 0.59 / 0.48	0.79 / 0.80 / 0.75	0.94 / 0.93 / 0.93	0.67 / 0.66 / 0.53

Active learning results**Figure 1: F1 Improvements with Active Learning**

There are also a few things we noticed that did not work. Ordinary data preprocessing techniques such as lemmatizing and mainly stopword removal actually reduced model performance in terms of accuracy on all four models. From reviewing the coefficients, we found that many times the tense and plurality of words actually matters, let alone a lot of the stop words. For example auxiliary verbs such as “could” and “should” often implies a problem needs to be corrected, and words implying contrast such as “but” and “however” are used to bring up readers’ attention before mentioning dissatisfaction. When these elements of language are removed, predicting whether a comment contains a problem becomes harder.

Apart from this, attempts on generating uncertain data from Neural network models and then re-train itself with resolved uncertainty does not show significant differences compared with training itself on more randomly selected samples. Results for both approaches have a F1 score fluctuate between 0.69 and 0.71 without significant differences. This could be because each time a neural network is trained, it restructures itself in a different way. With each perceptron (neuron) being a small classifier by itself, what is used to carry important knowledge to one network state might not hold as much value when the network is in a new state.

5. CONCLUSIONS AND FUTURE WORK

In conclusion, we could use models trained on one domain that classify certain sentiment components on other domains. We have tested doing problem detection between two dis-

tinctively different classes, and are confident about detecting other useful things such as suggestions or problem localizers. Results in the previous section have presented that with very little human intervention, each of the classifiers could regain a significant amount of its accuracy.

This is a very important step if we are to build a system that could promote students writing better reviews in different domains and different class settings. Furthermore, if we are to automate the grading process by involving inputs from peer assessment, we would certainly want to use features such as “how many suggestions are made” or “how many problems did the reviewer find” to gauge the quality of peer grading. Being able to analyze these features across peer assessments from different subjects becomes increasingly important.

Within this article, we mainly focused on transfer learning on traditional machine learning techniques, while there are many deep transfer learning techniques which could be utilized. With smaller datasets they might not have made much difference in terms of model accuracy. However, other researchers have shown that using layers in these neural networks trained on one dataset could be used as feature extractors for another. Examples of this are GloVe [32] and BERT [33], where both of these models are trained on a much larger dataset, resulting in exposure to a variety of knowledge, then later repurposed as feature extractors for other tasks.

In the future, we plan to explore the possibility of using transfer learning and active learning on neural network models and to continue building a review helpfulness evaluator across different subjects. In the long run, we would like to create a system that automatically assigns grades to students based on both numerical and textual peer assessments.

ABSTRACT

The goal of knowledge tracing is to track the state of a student's knowledge as it evolves over time. This plays a fundamental role in understanding the learning process and is a key task in the development of an intelligent tutoring system. In this paper we propose a novel approach to knowledge tracing that combines techniques from matrix factorization with recent progress in recurrent neural networks (RNNs) to effectively track the state of a student's knowledge. The proposed *DynEmb* framework enables the tracking of student knowledge even without the concept/skill tag information that other knowledge tracing models require while simultaneously achieving superior performance. We provide experimental evaluations demonstrating that DynEmb achieves improved performance compared to baselines and illustrating the robustness and effectiveness of the proposed framework. We also evaluate our approach using several real-world datasets showing that the proposed model outperforms the previous state-of-the-art. These results suggest that combining embedding models with sequential models such as RNNs is a promising new direction for knowledge tracing.

Keywords

Knowledge tracing, Recurrent neural networks, Matrix factorization, Matrix completion

1. INTRODUCTION

A central component in many computer-based learning systems, and in any kind of *intelligent tutoring system* (ITS), is a method for estimating and tracking a student's knowledge or proficiency based on the student's previous interactions with the system. For example, a student may interact with many different course materials (homework exercises, quiz/exam questions, textbooks and other course materials, etc.) over a potentially long period of time. As a result of these interactions (as well as other external factors) the student's knowledge and proficiency will dynamically evolve

over time [3, 13, 1, 12]. Tracking the state of a student's knowledge as it evolves can provide deeper understanding how the student is learning and which interactions (questions, textbooks, etc.) are most helpful, ultimately enabling the creation of a personalized learning environment tailored to provide an improved learning experience for the student.

Estimating student knowledge or proficiency from a sequence of student interactions poses two fundamental challenges. First, student proficiency evolves over time as the student interacts with the system. For example, the student might turn to textbooks in response to getting a particular question wrong, and then may be able to answer a similar question correctly afterwards. Alternatively, the student may gradually lose proficiency in some areas if long periods of time pass without using this knowledge (e.g., over long vacations). Thus, we cannot treat this as a static problem of estimating a student's knowledge, but must think of this as a dynamic tracking problem. A second and more subtle challenge is posed by the fact that the manner in which student proficiency evolves may be strongly influenced by the nature of the interactions. For example, when a student is posed a question that requires knowledge of a particular concept, we not only learn something regarding the student's proficiency, but the student may also learn something from the question. In this way, the interactions both provide information to help us track the student's knowledge while simultaneously inducing changes in the state that we wish to track.

In this paper we propose a framework for tracing student knowledge using only a sequence of student responses to questions (for an ensemble of many students). The framework consists of two core components: a (static) embedding network that learns fixed latent representations of questions from student-question interactions and a recurrent neural network (RNN) that dynamically tracks the hidden state corresponding to each student's knowledge over time from the student's sequence of interactions. Our main contributions are:

- A new knowledge tracing framework which exploits both the advantages of latent question embedding from response data and an RNN to track student knowledge;
- A framework that can track student knowledge without using the question-level concept/skill tags that other knowledge tracing models (e.g., DKT [13] and its variants) require, avoiding labor-intensive manual tagging;

Liangbei Xu and Mark Davenport "DYNAMIC KNOWLEDGE EMBEDDING AND TRACING" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 524 - 530

- A flexible framework that can also accommodate a variety of sequential modeling techniques (e.g., memory networks [28]) and can incorporate tag information and other features when available.

2. RELATED WORK

2.1 Educational data mining

Extracting useful information from the kind of educational data we consider was first studied within the *intelligent tutoring* community. Since the seminal work of [3], there has been a variety of efforts aimed towards understanding the cognitive processes that are most relevant in the context of an ITS, most of which aim to estimate students' proficiency based on their past interactions with the system with the aim of predict their performance on the new exercises/tests or customizing their learning materials.

Static models. Item Response Theory (IRT) is a standard framework for modeling student responses to questions dating back to the 1950s [20]. Perhaps the most common IRT model is the Rasch model [15]. This is a simple two-parameter model in which each student is modelled as having a particular skill level and each question has a particular difficulty, which is then paired with a logistic link function to provide predictions of the probability a student will answer a question correctly. There are natural multidimensional extensions of this and similar IRT models, which can be viewed as special cases of standard matrix factorization models ([19]) or more general factorization machine models [16]).

Sequential models. Most of the models described above involve estimating a fixed student-question embedding which is then used to predict future responses. However, we fully expect the state of a student's knowledge to change over time. To capture such dynamics, a natural approach is to incorporate dynamics in the model. One of the most popular models is Bayesian Knowledge Tracing (BKT), which employs a hidden Markov model ([3]) to model the process of mastering a particular skill. However, the BKT approach has some significant drawbacks. Most significantly, it models only a single skill or concept at a time. In practice, any particular question may be associated with a complex combination of different skills. To overcome this shortcoming, several alternative approaches have recently been proposed.

The most relevant attempt in this direction is the Deep Knowledge Tracing (DKT) framework [13]. The DKT approach was inspired by recent progress in RNNs and deep RNN architectures. RNNs are a family of neural networks tailored for sequential prediction problems [22]. In recent years deep RNN architectures have been shown to outperform many classical models in many application areas, including natural language processing and session-based recommendation system. DKT is the first model to use RNNs to track student knowledge. DKT uses a one-hot encoding of skill/concept tags and associated responses as input and trains the RNN to predict the future student response. An extension of DKT is the Deep Hierarchical Knowledge Tracing (DHKT) [21], which extended DKT to incorporate problem IDs in addition to concept tags.

However empirical experiments in [26, 23, 24] show that DKT does not appear to result in substantial improvement over many simpler models from classical IRT whose parameters and inferred states are psychologically meaningful. It is worth noting that the IRT variants considered in [26, 23, 24] use problem IDs as identifiers instead of skill IDs for DKT. Since multiple problem IDs can be tagged with the same skill IDs, we generally find that skill IDs repeat much more frequently than problem IDs. Thus, a comparison using skill IDs would likely be more favorable to a recurrent/sequential model like DKT. Of course, in considering only skill IDs we lose the ability to learn/exploit question-level information such as question difficulty. Moreover, producing skill IDs for each question requires substantial human effort and is often not feasible in practice. Furthermore all the experiments in [26, 23, 24] consider the 'New Student' evaluation protocol, which keeps a portion of the students as training sets and test on new students. Such an evaluation scenario may not be particularly meaningful in a real-world ITS and does not favor penalization models such as IRT, though online evaluation in [23, 24] mitigates such bias. Thus, the comparison study in [26, 23, 24] is not entirely satisfying and leaves open many questions regarding the potential benefits (or lack thereof) of deep RNNs for knowledge tracing.

Hybrid models. There are also several attempts to combine static models and sequential models to exploit advantages from both approaches, such as the FAST model in [5] and the LFKT model in [9]. In [10], these two approaches are compared and the experimental results show that these two hybrid models do not outperform a simple IRT model. The authors conjecture that the lack of improvement is due to a confounding between item identity and the question position in a (nearly deterministic) sequence of questions. In contrast to these more pessimistic results, in this paper we propose a hybrid model and show that it can harness the advantages from both static and sequential models in a way that outperforms both.

2.2 Session-based recommendation systems

A closely related application to knowledge tracing is that of predicting a user's preference for various items in a recommendation system. Among various recommendation systems, session based recommendation is the most closely related to knowledge tracing. For example, a session-based recommendation model, GRU4Rec, is proposed in [6] that has a similar architecture as DKT. However, GRU4Rec does not consider user identifications as inputs. An alternative approach – the Recurrent Recommender network (RRN) [25] – is capable of both modelling the seasonal evolution of items and tracking the user preferences over time. RRNs use a matrix factorization to model the stationary component of the user and item embeddings, and then two Long Short-Term Networks (LSTMs) to track the dynamic component of these embeddings.

Though similar, there are some notable differences between product recommendation and knowledge tracing. First, user preferences tend to change much more slowly compared to student knowledge. Second, student interactions with questions have a significant impact on student knowledge, while in contrast interactions with an item (watching a movie,

buying a product, etc.) typically have a mild impact at most on user preferences. Third, in a recommendation context, user responses may contain important implicit feedback [7]. For example, we can conclude that a user will watch a movie or buy a product because he/she likes it, even if the user does not give explicit feedback. However, students typically have limited freedom to choose which questions to answer. These differences have important algorithmic implications.

3. THE DYNEMB FRAMEWORK

3.1 System architecture

In this section we describe a novel framework for tracking student knowledge, dubbed *DynEmb*, that learns a *static* question embedding but exploits *sequential* models of the temporal dynamics of student-question interactions to track the knowledge states of the students. We will represent our training data as a sequence of interactions of the form $\mathcal{R}_t = (s_t, q_t, r_t, o_t)$. Each interaction \mathcal{R}_t involves a student s_t and a question q_t . We assume there are M questions and N students. The response to the question is denoted r_t , which is most commonly a correct/incorrect binary outcome or occasionally a numerical score. In this paper we focus mainly on the binary case, but the underlying framework can easily extend to the more general setting. Finally, we let o_t denote other information about the interaction that may be relevant, including – but not limited to – time stamps, questions tags, platform (e.g., paper, computer, mobile, etc.), and question text descriptions.

The goal of *DynEmb* is to predict student responses to future questions given a historical sequence of interactions $\{\mathcal{R}_i\}_{i=1}^n$. Specifically, given a new student-question pair (s_t, q_t) and any additional information o_t if available, our goal is to predict r_t . *DynEmb* has two main components, each of which are trained independently (see Figure 1). The first component *QuestionEmb* generates a d -dimensional *question embedding* $W_{q_t} \in \mathbb{R}^d$ from $\{\mathcal{R}_i\}_{i=1}^n$ using standard matrix factorization techniques described in more detail below. The second component *StudentDyn* learns to track each student’s knowledge state using a sequential model that takes the student’s past sequence of question embeddings $\{W_{q_i}\}_{i=1}^{t-1}$ and responses $\{r_i\}_{i=1}^{t-1}$ as inputs and produces a dynamic student embedding $Z_{s_t}(t) \in \mathbb{R}^d$. The sequential model could be a “vanilla” RNN, a long short-term memory (LSTM) network, a gated recurrent unit (GRU), a memory network with attention, or others. In this work we use an LSTM in the *StudentDyn* component by default. After obtaining the (static) question embedding W_{q_t} and the (dynamic) student embedding Z_{s_t} , the predicted probability of a correct response is computed via

$$\hat{r}_t = \phi(\langle W_{q_t}, Z_{s_t}(t) \rangle + b_{q_t}), \quad (1)$$

where b_{q_t} is a scalar that represents a bias learned for each question and ϕ is a sigmoid activation function. We describe these components in further detail below.

QuestionEmb. The *QuestionEmb* component uses an ℓ_2 -regularized biased matrix factorization model to learn a static latent embedding for the questions. More specifically, in this component we learn both a question embedding W and a student embedding Z , where $W \in \mathbb{R}^{N \times d}$ is a matrix whose

columns correspond to the question embedding vectors (the W_q ’s) and $Z \in \mathbb{R}^{M \times d}$ is a matrix whose columns correspond to the student embedding vectors (the Z_s ’s). These are learned via the following optimization problem:

$$\arg \min_{W, Z, b, c} \sum_{t=1}^n \mathcal{L}(r_t, \phi(\langle W_{q_t}, Z_{s_t} \rangle + b_{q_t} + c_{s_t})) + \lambda (\|W\|_F^2 + \|Z\|_F^2), \quad (2)$$

where b and c are vectors of question and student “biases” respectively, λ is the regularization parameter, and $\mathcal{L}(y, x) = -(y \log(x) + (1 - y) \log(1 - x))$ is the log loss function. This is inspired by the observations in [27] that if the question embedding W is static, then one can still use conventional matrix factorization to recover W , even though the other factors Z may actually be changing over time. Finally, we note that while (2) is a non-convex optimization problem, simple optimization algorithms exist that provably converge to a global minimum [8, 4].

StudentDyn. The *StudentDyn* component uses an RNN to sequentially generate a student embedding after each interaction. For the case of a binary response, r_{t-1} , the input to the recurrent neural network is the Kronecker product of the question embedding learned by the *QuestionEmb* component ($W_{q_{t-1}}$) and the vector $[r_{t-1}, 1 - r_{t-1}]^T$. At time step t , an interaction between student s_t and question q_t is predicted via the model in (1), and the RNN is trained to predict r_t . The dynamic student embedding $Z_{s_t}(t)$ is the internal hidden state of the RNN, which is then combined with W_{q_t} via (1) to obtain our final prediction.

3.2 Model training

To train *DynEmb*, we adopt a two-phase pretraining strategy. We first train the question embedding in the *QuestionEmb* component. We then feed the learned question embedding to the *StudentDyn* component to train the sequential model. Note that we keep the question embedding W and the biases b fixed when training the *StudentDyn* component. This embedding pretraining strategy not only speeds up the training process, but also produces better prediction performance compared to end-to-end training (see Section 4.4 for an experimental justification). Similar pretraining strategies are widely used in learning complex models (e.g., for machine translation [14] and sentiment analysis [17]).

Compared to DKT [13], DKVMN [28], and other sequential knowledge tracing models, the explicit question embedding learned directly from interactions based on matrix factorization seems to be more robust. In fact, in our experiments we have observed that if we replace the (frequently repeating) concept/skill tags in DKT and DKVMN with the (much less frequently repeating) question identifiers, then both DKT and DKVMN will have significant performance degradation and require intensive computational resources to train. However, our model can track student knowledge using the pretrained question embedding instead of concept/skill tags. This allows our approach to exploit question difficulty information and scales well, especially when concept/skill tags are not available.

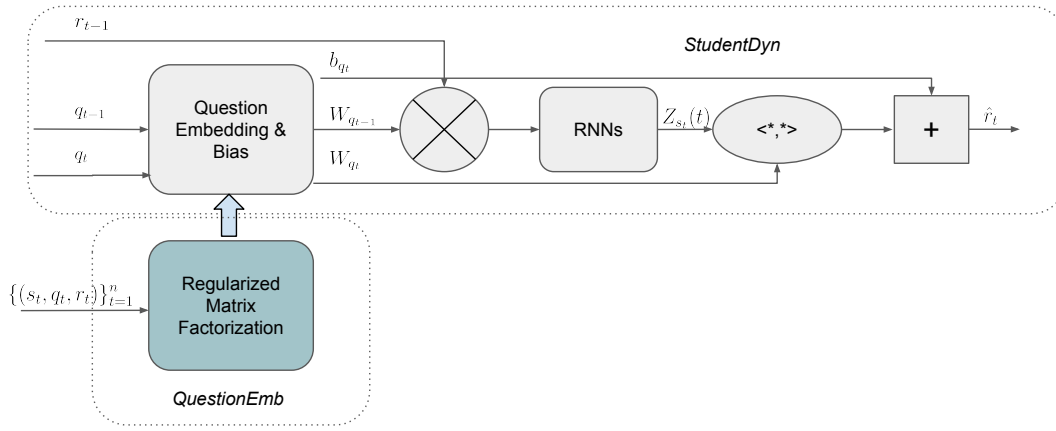

Figure 1: Architecture for *DynEmb*. First we train *QuestionEmb* to obtain question embedding W and bias b . Then we train the RNNs using past item embedding $W_{q_{t-1}}$ and response r_{t-1} as inputs to track student knowledge.

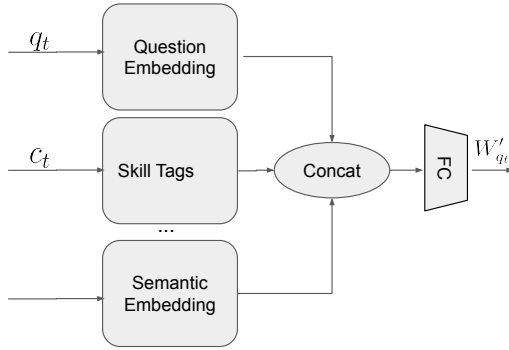

Figure 2: Multiple input fields.

3.3 Integrating skill tag information

If manually-labeled skill tag information is available for each question, then it is convenient and beneficial to incorporate this information into the *DynEmb* framework. However the question latent space learned via the matrix factorization might be different from the latent space constructed by manual labeling. One simple method to exploit both approaches consists of concatenating the two latent question embeddings to form a new latent question embedding. The skill tags can be one-hot encoded. To further exploit the hierarchical relationship between questions and skill tags, we initialize a question’s embedding by the one-hot encoding of its corresponding skill tag, and put an additional ℓ_1 regularization on the objective in (2) to promote sparsity.

To control the dimensionality of the latent space, the concatenated embedding is followed by a fully connected (FC) layer with ReLU activation. This kind of integration scheme can be found in [2] and also enables easy incorporation of additional embeddings/fields, e.g., semantic embedding from question text.

Finally, the *StudentDyn* component uses an RNN to sequentially generate a student embedding after each interaction using this modified question embedding just as before. See Figure 2 for additional details.

4. EXPERIMENTS

In this section, we experimentally validate the effectiveness of the proposed *DynEmb* model on two tasks: prediction of response correctness for existing students and prediction of response correctness for new students. By conducting experiments on several data sets each and comparing with the relevant baselines, we show that:

1. *DynEmb* outperforms DKT by up to 5.43% and 3.74% in predicting the next response in the ‘New User’ and ‘Most Recent’ evaluation settings respectively (see definition in Section 4.1);
2. The performance of *DynEmb* is stable with respect to the dimensionality of the item embedding;
3. The proposed embedding pretraining strategy is a key component of the success of the *DynEmb* approach.

4.1 Experimental setting

We consider the following baselines:

- Algorithms that compute a static embedding: in this category, we compared with BMF [19]. We compare to both offline and online BMF.
- Knowledge tracing based on RNNs: we compare with the state-of-the-art DKT algorithm [13].

We report the Area Under the ROC Curve (AUC) for comparing the predicted probabilities of correctness for each response. AUC is threshold agnostic, and is widely used in the knowledge tracing literature.

We use two evaluation methods. The first is online response prediction for new users [13, 23]. In this setting, students are first split into training and testing populations. Each model is first trained on the training population. Then for each time $t > 1$ in each testing student’s history, we train the student-level parameters in the model on a new student, including both the training population and the first $t - 1$ interactions of the student history, computing the probability

that the t^{th} response is correct. In practice, we find that re-training and testing after each response is not computationally feasible for large datasets, in which case we perform online response prediction in batches. We denote this evaluation method the ‘New User’ setting. Our second method is to consider online response prediction for the the most recent interactions as in [23]. The procedure here, denoted the ‘Most Recent’ setting, is the same as in the ‘New User’ setting except that we consider only the most recent interactions for our testing population as the testing data set.

4.2 Experiment 1: Future response prediction

In this experiment, the task is to predict students’ response. The prediction task is: given all interactions up to time t , given the student s and question q involved in the interaction at time t , what is student s ’s response (correct/incorrect) to question q ?

We use the following data sets to evaluate performance on this task.

ASSISTments. This data set was gathered from ASSISTments’s skill builder problem sets, where students learn by working on similar questions until they can respond correctly n (usually 3) times in a row [11]. We use two one the provided data sets, “ASSISTment09” and “ASSISTment12.” Note that the authors updated “ASSISTment09” in 2017 (first found in [26]).

Cognitive Tutor. In the 2010 KDD Cup Challenge, the PSLC DataShop released several data sets from Carnegie Learning’s Cognitive Tutor in (Pre-)Algebra from the years 2005-2009 [18]. We use three of the “Development” data sets, “Algebra I 2005-2006,” “Algebra I 2006-2007,” and “Bridge to Algebra I 2006-2007.”

Preprocessing of data sets. As noted in [23], there are multiple records duplicating a single interaction (represented by a unique *order.id* value) in “ASSISTment09.” These duplicate rows arise when a single interaction is aligned with multiple skills. This provides DKT models access to the ground truth when making their predictions, which can artificially boost prediction results by a significant amount. We adopt two strategies to clean the data. The first is to discard rows duplicating a single interaction (as in [23]); the second is to combine these duplicating rows into a single row with a new skill tag as suggested by [26]. In this paper we removed duplicate and multiple-skill repeated records in all data sets to ensure fairness for the purpose of comparison. We also removed “not original” records as suggested by [26]. We do similar cleaning operation on the other data set “ASSISTment12”. For the Cognitive Tutor data sets, we form problem identifiers from the concatenation of the “Problem Name” and “Step Name” fields.

Implementation details. The dimensionality of the input to the RNNs in *DynEmb* is fixed at 100. The ℓ_2 regularization parameter in the *QuestionEmb* component is chosen using cross-validation based on standard BMF. The hyperparameters in the *StudentDyn* component are the same as DKT and chosen by cross-validation.

Results. Table 2 compares the results of *DynEmb* with the baseline. We observe that *DynEmb* significantly outperforms the best baseline in all datasets in terms of AUC on the three datasets up to 5.43%.

4.3 Experiment 2: Robustness to embedding dimensionality

In this section, we study the effect of the dynamic embedding dimensionality on the tracking performance. In this study we use the “ASSISTment09” and Cognitive Tutor “Algebra I 2005” (“CT05” for short) datasets, which have the smallest number of interactions from the two tutoring systems respectively. The effect on other datasets is similar and omitted for the sake of brevity. We will test on the response prediction task. As we can see from Figure 3, the performance by AUC of *DynEmb* is quite stable over a wide range of embedding dimensionalities. This robustness is an additional attractive feature of our approach.

Figure 3: Performance versus embedding dimensionality.

4.4 Experiment 3: Embedding pretraining vs. end-to-end training

In this section we demonstrate why *DynEmb* uses pretraining for the question embedding. The dataset used in this section is “ASSISTment09.” We use the “Most Recent” evaluation method. In Figure 4, we can see that end-to-end (E2E for short) training (with/without pretraining the question embedding) will cause over-fitting, while the learning curve of proposed pretraining strategy does not suffer from over-fitting or under-fitting. Of course, another advantage of pretraining is its improved computational efficiency. The combination of these two factors provides powerful evidence for choosing pretraining over an end-to-end training strategy in this framework.

4.5 Experiment 4: Visualizing question embedding

Though the latent space of the question embedding learned via matrix factorization is not explicitly aligned with the latent space formed by the manually-labeled skill tags that were provided, the proposed question embedding initialization and sparsity promotion is remarkably effective at aligning the question embedding space with the manually constructed skill embedding space. This provides additional se-

Table 1: Overview of data sets.

Data set	Number of				Ratio of correctness	Description

mantic meaning for the learned question embedding, which improves model interpretability. Figure 5 shows clear clustering of question embedding with respect to the associated skills (indicated by skill identifiers).

5. CONCLUSION AND DISCUSSION

In this paper we presented a framework to track student knowledge in an ITS by utilizing techniques from matrix factorization/embedding and RNNs. Our framework can track student knowledge without the concept/skill tag information required by other knowledge tracing models, e.g., DKT [13] and its variants. This avoids labor-intensive manual tagging. Taking advantage of additional latent question embeddings, our framework outperforms recent state of the art knowledge tracing models using RNNs. By constructing an embedding of the questions via matrix factorization in addition to skill tags, our framework can fuse question-level

and skill-level information. The *DynEmb* framework is also flexible in that it can accommodate various matrix factorization techniques and dynamical models, which makes it a promising avenue for future research and development of algorithms for knowledge tracing.

However, in the context of a real-world implementation, several challenges remain regarding how to design a practical *DynEmb* based system for knowledge tracing. For example, developing a method amenable to deployment in an online setting will require additional algorithmic improvement. Another challenge concerns how to incorporate additional sources of auxiliary information not considered here, such as question text or details about additional student interactions with an ITS (browsing history, textbook interactions, etc.) to best exploit all of the information that might be available. We believe that the *DynEmb* framework provides a natural platform to address such challenges.

ABSTRACT

In order to effectively grade persuasive writing we must be able to reliably identify and extract argument structures. In order to do this we must classify arguments by their structural roles (e.g., major claim, claim, and premise). Current approaches to classification typically rely on statistical models with heavy feature-engineering or on deep neural-networks that do not consider prior knowledge or other secondary features. Little research has been carried out to investigate if we can incorporate features into deep models to address AM tasks. In this work, we propose to incorporate lightweight features into deep models to classify argument components. We experimented with two state of the art (SOTA) approaches: 1) linear-Long-Short-Term Memory (LSTM) models with concatenated feature vectors; or 2) Directed Acyclic Graph (DAG) structured LSTMs. In our models we incorporated the features of argument position (e.g., if the argument is in the first paragraph) and prior knowledge of discourse indicators (e.g., in conclusion, for example). We use two baselines in our work: 1) prior work using SVM models with heavy feature engineering; 2) traditional linear-Bi-LSTMs with no task-specific features.

Our results show that with a comparatively small number of lightweight features, both linear-Bi-LSTMs and DAG-Bi-LSTMs outperform SVM models that depend on more heavy feature engineering, and outperform linear-Bi-LSTMs with only general word embedding features. These results suggest that incorporating task-specific elements into deep models may potentially benefit argument mining tasks.

1. INTRODUCTION

Current automated essay grading systems are typically focused on the syntactic and semantic analysis of written arguments via Natural Language Processing (NLP) techniques (as in [7, 23, 3]). These

systems are typically designed to evaluate arguments on the basis of: general readability (e.g., the number of prepositions and relative pronouns or the complexity of the sentence structure); shallow semantic analysis (e.g., lexical semantics or the analysis of the relationship among named entities); and syntax analysis (e.g., grammatical analysis). To the extent that argument structures considered in this work have been focused on the limited identification of individual components (e.g., hypothesis statements [4]), or on manual analysis by human experts [14], which is costly and time-consuming. Few existing systems perform any automatic analysis of the argumentative structures or seek to identify structural flaws due to the lack of an auto-extraction mechanism in the system.

In order to parse arguments it is necessary to extract the basic components. Extracting argument structures (EAS) is one of the essential tasks of argumentation mining (AM). EAS can be divided into three sub-tasks: 1) **argument component identification (ACI)** breaking down the text into argument units; 2) **argument component classification (ACC)** of classifying argument component (ACs) into types; 3) **argument relation identification (ARI)** of identifying the relationships between each pair of ACs. Prior researchers have focused on different subsets of these tasks (e.g., [27] addressed ACI, ACC, and ARI separately, [24] jointly modeled ACI and ACC) or built end-to-end models that address them sequentially (e.g. [18]). Our goal in this work, by contrast, is to investigate how to incorporate task-specific features into deep learning models and whether those features can improve our models' performance on the task of ACC. We carried out our work using an argumentation schema developed by Stab and Gurevych on a corpus of 402 persuasive essays (PE) [27]. As part of this work, we replicated their work on ACC and used it as a baseline model.

Most current approaches to ACC either rely on heavy feature engineering [27, 16, 22, 12] or use deep models that only consider pre-trained word embeddings with no other secondary features [19, 24, 11]. Little research to date has been focused on incorporating prior knowledge or lightweight features into deep models for AM tasks. To the best of our knowledge, Lugini and Litman carried out the only work that adds features into LSTM based models to address ACC on the argument dataset of classroom discussions [13]. In that work, they considered a set of features including semantic-density features (e.g. the number of pronouns), lexical features (e.g., uni-gram and bi-gram), and syntactic features from speech tags. They combined the feature matrix and LSTMs hidden output for classification. They showed that the features boosted the deep model performance.

In our work, we investigated whether or not it is possible to incor-

Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 531 - 537

Figure 1: An example of DAG LSTM modeling an AC.

porate lightweight features into deep models to address ACC on PE dataset with different feature sets and deep models. In this work we considered prior research on the prior knowledge of discourse indicators and position features. The discourse indicators have been shown are potential features for identifying the argumentative section of online product reviews [30]. Researchers have also demonstrated that the structural features of AC position (e.g., if the AC shows in the introduction, if an AC is the first sentence of one paragraph) and token statistics (e.g., number of tokens of an AC) are the most effective features for AC classification [27]. For this study we only considered the position information for ACs. We chose to focus on these two features because these two are the most informative and also require the least amount of feature-engineering.

For our deep models, we experimented with Bi-LSTMs. We encoded the incorporated features by one-hot encoding, computed the element-wise summation of feature vectors, and then combined feature vectors with Bi-LSTMs output for prediction. This approach is the same as the work in [13]. We also considered bidirectional DAG-Structured Recurrent Neural Networks (RNNs) to incorporate features. **DAG-RNNs**, also known as Neural Lattice Language models, are an extension of linear-chained RNN models that can consume DAG-structured input [32]. If we treat the text as a linear path, the prior knowledge and secondary features can be added as new edges on the path to form a DAG structure. The discourse features are connected to the parent- and child- nodes of the related tokens, similar to the work of [32]. For position features, we simply connected them with the two special sequence delimiters which indicate the beginning and end of the sentences. Figure 1 shows an example of DAG input with discourse indicators of “FROM_THIS_POINT_OF_VIEW” and “I_FIRMLY_BELIEVE_THAT” in red and position features of “IN_INTRODUCTION” and “IS_LAST_SENTENCE” in green. The original input is in the blue nodes. Token “-B-” and “-E-” are special sequence delimiters. The nodes are indexed in topological order, as this is the order in which the one-directional DAG model consumes the input sequence. For bidirectional DAG models, we simply reverse the order. The intuition behind this approach is that it mimics how humans read and annotate essays as humans can incorporate linguistic intuition to determine the role of the ACs in written argumentation. For example, if a sentence appears to be the last sentence of the introduction in a five-paragraph essay, it most likely contains the author’s standpoint, i.e., claim.

DAG-RNNs have been used to incorporate linguistic knowledge (e.g., the non-compositional phrase in the form of n-gram) for sentiment classification [32]. They have also achieved SOTA results in many other NLP tasks such as neural machine translation [28], speech translation [25], and language modeling [2]. In this work,

we utilized LSTMs, a special kind of RNN and building off Zhu et al.’s work [32], we implemented a DAG-LSTM in Tensorflow with a different hidden state bagging function (discussed in section 4).

Our results show that linear-Bi-LSTMs with no task-specific features performed worse than traditional models. However once we incorporated our two features, both the linear-Bi-LSTMs and DAG-Bi-LSTMs outperform general Bi-LSTMs with no features and they outperform other models that rely on heavy feature-engineering. DAG-Bi-LSTMs slightly outperform the linear-Bi-LSTMs when considering both features. The linear-Bi-LSTMs with only position features yield the best results.

The significance of this work is as follows. 1) Our work serves as the basis for automated essay grading systems, and can be applied to extract argument structures for detecting structural flaws. 2) We addressed a common issue in NLP that deep models tend to yield lower performance on small datasets. We showed that deep models can benefit from lightweight features and yield better performance. 3) We experimented with DAG-LSTMs to incorporate features on text classification tasks. We showed that it could be a promising architecture to incorporate features into sequence models. 4) We tested the same approach used in [13] to combine features with LSTMs on a different dataset. Our results are consistent with their work.

2. RELATED WORK

2.1 AC Classification

Most of the prior work on AC classification relies on traditional classification models and heavy feature engineering. In [27], researchers applied multiclass SVMs to classify ACs using structural, lexical, syntactic, discourse indicator, and contextual features. They obtained an F1 score of 0.794 on the PE corpus. In [26] and [18], authors performed classification task on a small portion of the PE dataset, again relying on extracted features. In [10], Namhee et al. analyzed online comments to identify and classify subjective claims using lexical and syntactic features. In [16], researchers worked to classify ACs on legal documents using extracted features while Niall et al. applied kernel methods for argument detection and classification on AraucariaDB dataset [22]. Different from the above, we only considered prior knowledge of discourse indicators and structural information of position features.

Many researchers have begun to explore the application of deep neural-network models to argument mining. In [11], authors experimented with CNN and RNN models to detect the claims [1] and evidences [21] on Wikipedia datasets. Potash et al. proposed a joint sequence-to-sequence model with attention to predict the links between ACs and classify ACs on the PE dataset, where they consid-

ered the sequential nature of ACs [19]. In our work, by contrast, we focused on incorporating prior knowledge to deep neural-networks to classify the ACs alone.

To the best of our knowledge, research from [13] is the only work that combines feature engineering and deep models to address ACC on classroom discussion. They showed that SOTA deep models with only pre-trained embeddings performed poorly on their dataset. However, by including secondary features they improved the performance substantially. The features included: semantic-density features (e.g., number of pro-nouns, descriptive word-level statistics, number of occurrences of words of different lengths), lexical features (e.g., tf-idf feature for each unigram and bi-gram, descriptive argument move-level statistics), and syntactic features (e.g., unigrams, bigrams, and tri-grams of part of speech tags). In their work, they experimented with Convolutional neural network models and LSTMs. Their results showed that the model’s performance was improved after adding the secondary features. In our work, we considered the same approach to incorporate features into linear-LSTMs and compare the model performance with DAG-LSTMs.

2.2 DAG-RNNs

DAG-RNNs, also known as Neural Lattice Language (NLL) models, are extensions of chain-structured RNNs [32, 28]. These models, first proposed by Zhu et al. in [32], leverage DAG structures to incorporate external semantics such as n-gram sentiment tags and expert annotations to improve performance on sentiment classification. Su et al. introduced NLL-based Gated Recurrent Units (GRUs) to encoder multiple word segmentation of Chinese text for translation [28]. Sperber et al. later used NLL-based GRU models to consume word lattices from the up-stream modes of the speech recognizer for speech translation [25]. These lattices were annotated with posterior probabilities on the alternative translation paths. And finally, in [2], researchers demonstrated that the NLL models outperformed the LSTM-based models at the task of language modeling when incorporating multi-word phrases (n-grams) and multiple-embeddings for polysemy. However, little research has been done to utilize DAG-RNNs to integrate features for AM tasks.

3. DATASET

The PE dataset was developed by [27]. It contains 402 essays from the online community *essayforum*¹. The forum provides writing feedback for different kinds of text. Students can post practice essays for standardized tests in the community and obtain feedback about their writing skills. The dataset was randomly selected from the *writing feedback* section of the forum. The dataset comes with three argument components: *major claim* indicating the author’s standpoint on the given controversial topic; *claim* of sub-standpoints that supports (“for”) or attacks (“against”) the major claim; *premise* that is the reason of the argument which supports or attacks the claim. Table 1 shows the class distribution of the PE corpus. The average number of tokens in *major claims*, *claims*, and *premises* are 19, 23 and 21, respectively.

	Major Claim	Claim	Premise
Train & Dev	598	1202	3023
Test	153	304	809

Table 1: Number of instance in each class

Figure 2: An unit of DAG-LSTM.

4. METHODS

4.1 Linear-Bi-LSTMs

In traditional Bi-LSTM models, ACs are encoded using Glove embeddings [17] that are obtained from training on large Wikipedia datasets. The encoded ACs are fed to Bi-LSTMs, and the last hidden states are passed to the softmax layer for prediction. To incorporate features, we used a one-hot vector to represent each feature and summed up the features vectors that are related to an AC. For example, if we have a total of three features in the feature space that are “if an AC is in the introduction”, “if an AC is in the conclusion”, and if an AC contains discourse indicator of “in conclusion”. We use one-hot vectors to represent three features as [0, 0, 1], [0, 1, 0], and [1, 0, 0], respectively. When we have one example AC that contains a discourse indicator of “in conclusion,” and this AC is in conclusion paragraph, we sum up two feature vectors by elements to get a vector of [0, 1, 1], which represents the feature for this AC. Then we concatenate the vectors on the hidden output of Bi-LSTMs for final prediction. The same approach has been used in [13]

4.2 DAG-Bi-LSTMs

We implemented the DAG-Bi-LSTMs using the TensorFlow platform.¹ The DAG-Bi-LSTMs in our work is similar to the models described in [32]. However, we applied a different hidden state merge function. While Zhu et al. used binarization, we elected to sum the parent hidden states as suggested in the TreeLSTM work [29]. Intuitively, by summing the previous states, we expect the DAG-models to learn both the summarized linear history and the incorporated knowledge. We used the same one-hot method to encode the incorporated features.

For sequential inputs the linear-LSTM models calculate hidden states h_t and cell states c_t based upon the proceeding hidden state h_{t-1} , cell states c_{t-1} and the input embedding e_t of token x_t as:

$$h_t, c_t = LSTM(h_{t-1}, c_{t-1}, e_t, \theta) \quad (1)$$

The primary difference between DAG- and linear- LSTMs is that the former can have multiple parent and child states, as shown in Figure 2, while the latter cannot. Given a DAG input, h_{p_i} indicates a set of parent states at t time step, where $i = 0, 1, \dots, or n$ and $p_i \in P$. The DAG model first gathers its parent hidden states h_{p_i} and then sums over the parents’ hidden states and over the parents’ cell states as follows:

$$h_{P_t} = \sum_{p_i \in P_t} h_{p_i} \quad c_{P_t} = \sum_{p_i \in P_t} c_{p_i} \quad (2)$$

¹We also experimented with DAG-Bi-Gated Recurrent Units, but DAG-Bi-LSTMs yielded better results.

The remainder of the DAG process is similar to that of linear-Bi-LSTMs in that h_{P_t}, c_{P_t}, e_t are fed to standard LSTM unit to generate new hidden, cell states of h_t, c_t , which are then copied to the child states. Finally, the last hidden states are fed to Multi-Layered Perceptrons (MLPs) for prediction.

4.3 Prior Knowledge and Features

In this work, we considered the prior knowledge of discourse indicators and the AC position features. In prior work [27], Stab and Gurevych collected a list of hand-crafted features for ACC tasks, including lexical, structural, discourse indicator, contextual, syntactic, etc. The detailed explanations of the features can be found in Section 5.3.1 of [27]. For discourse indicators, they include five categories: *forward indicators* (e.g., “therefore”); *backward indicators* (e.g., “because”); *thesis indicators* (e.g., “in my opinion”); *rebuttal indicators* (e.g., “although”); and *first-person indicators* (e.g., “I”, “me”). For the position features, we annotated sentences if they were the first/last sentence and if they showed up in the last/first paragraph. The annotations are in the *special* n-gram form (e.g., “IS_LAST_SENTENCE”, “_THEREFORE_”) so that they are distinguished from original corpus. We also experimented with annotating the discourse indicators by category, such that the forward indicators were annotated as “FORWARD_INDICATORS”.

5. EXPERIMENTAL SETUP

We carried out a series of experiments using the same static training/testing split as in prior work [27]. Since the corpus does not have a designated development set, we used stratified sampling to select 15% of the training set to tune our hyper-parameters and reported our final results on the designated test set. We ran each experiment five times and reported the average Macro-F1 score of the test dataset.

We carried out four distinct experiments: **Base-SVMs**, which replicates the work in [27] with multiclass SVMs using polynomial kernels on a set of features; **Base-LSTMs**, which are baseline models of general Bi-LSTMs with no secondary features; **LSTMs** and **DAG-LSTMs** refers to Bi-LSTMs and DAG-Bi-LSTMs with task-specific features.

We used a grid search for hyper-parameter tuning, and we used the same set of parameters across all the models. We used 300-dimensional GloVe embeddings [17]. Tokens not present in the pre-trained embeddings or not features were randomly initialized with uniform samples from range $[-\sqrt{\frac{3}{dim}}, \sqrt{\frac{3}{dim}}]$ [15] where dim is the dimension of the embeddings 300. All of the tokens in the test and dev sets but not in the training set have one unique random embedding. The embeddings were fixed during training. We then used the Adam optimization algorithm [9] with a learning rate of 0.005, a batch size of 32, a layer LSTM with a hidden size of 64, and a drop out rate of 0.2, and a layer tanh-MLP with a hidden size of 64.

6. RESULTS & DISCUSSION

In this section, we will discuss the overall results. Later we will talk about how each feature impacts the linear-LSTMs and DAG-LSTMs by comparing them with traditional SVMs and linear-LSTMs with no task-specific features. In the end, we will compare the performance of linear-LSTMs and DAG-LSTMs.

6.1 Overall Results

Table 2 shows the results of each experiment and our baseline metrics. The standard deviations of the deep model results are all less than 0.009 over the runs. The first three columns show our benchmark, Stab and Gurevych’s results with SVMs on: all features, structural features alone (including AC position in the document and token statistics), and contextual features alone (including discourse indicators and the number of noun and verb phrases in an AC). The next two columns show two of our baseline models: Base-SVMs and Base-LSTMs. Then the rest shows the linear-LSTMs and DAG-LSTMs with the two features together and separately. *Pos* includes the position features are considered, while *dis* refers to the discourse indicators were incorporated, and *Pos-dis* indicates that both features are used.

Overall, for linear-LSTMs with only position features return the best macro-F1 score of 0.805 across the board. DAG-LSTMs with both position and discourse features return a very close score of 0.802. Drilling won, linear-LSTMs with position features also yield the best F1 score for claim and premise components, especially for claim components, the F1 score is increased by 23% over the base-LSTMs and increased by 4.5% over base-SVMs. For major claims, the SMVs from prior work still have the best F1 score.

Thus for traditional models with heavy feature engineering, our Base-SVMs are close to Stab and Gurevych’s result (SVMs) but with a lower F1 score on major claims. This may be due to minor differences in our feature extraction or the different experimental setting. Among three deep models, the base-LSTMs with only pre-trained word embeddings perform very poorly, and all the F1 scores are much lower than the SVM models, which is not very surprising because of the small amount of data. The trained models do not generalize well on test data. This may also be due to the fact that the pre-trained embeddings are obtained from training models on a large corpus of Wikipedia data [17], which can be thought of prior knowledge. However, Wikipedia is very different from the PEs, the writing is generally more formal; it is a product of collaborative work; and is heavily edited. PEs are most likely composed by non-native English writers. Thus the base-LSTMs with glove embeddings may not able to catch the semantic meaning in the PEs.

However, once we incorporated the position and discourse features, we obtained a very high Macro F1 score. We have F1 of 0.801 and 0.802 for linear and DAG models, a 16% improvement over Base-LSTMs with no features (0.633). These results imply that both models can utilize task-specific features to boost performance. When we compare deep models with heavy feature engineering based SVMs, we find that the deep models with only two features outperformed the SVMs with heavily features Engineering, which suggests that combining little features with deep models can improve the learning on AM tasks.

6.2 Position Features

When adding position features, both the linear models and DAG models outperformed the SVMs and base-LSTMs. The linear models return the best results. In fact, after incorporating position features, the major claims that were previously misclassified as premises by the Base-LSTMs were now either classified as claims or major claims in the linear and DAG models. However, while adding the position features improves the tasks on identifying the claims and major claims, they are not good at distinguishing the two. Looking deeper, the resulting models tend to be biased towards the major claim classification, especially for claims that show up in the introduction or conclusion. One possible explanation for this is that

	SVMs (Stab et al.)			Base-SVMs	Base-LSTMs	LSTMs			DAG-LSTMs		
Features	All	Pos	Dis	All	None	Pos-Dis	Pos	Dis	Pos-Dis	Pos	Dis
Major claim	.891	.803	.656	.844	.625	.832	.823	.650	.852*	.845	.645
Claim	.611	.551	.248	.640	.455	.670	.685*	.428	.659	.668	.498
Premise	.879	.870	.836	.886	.819	.903	.907*	.820	.896	.886	.797
Macro-F1	.794	.741	.580	.790	.633	.801*	.805*	.633	.802	.799	.647

Table 2: Results on classifying ACs on PE corpus. “All” column refers to the eight type of features in [27]. “Pos” column indicates the models with position features. “Dis” columns shows the model results with discourse features. * means significant improvement over Linear-LSTMs with no features. Bold indicates the best result per row.

the position features dominate the feature space in the PE dataset; models pay too much attention to the position features and too little attention to the semantic context.

Our results are consistent with prior work which has suggested that position features play an important role in classifying ACs on the PE dataset. As shown in Table 2 with only position features, the traditional SVMs can reach a macro F1 score of 0.741. The utility of this feature is relatively intuitive. In five-paragraph essays, the major claims usually show up in the first or last paragraphs. And in our PE dataset, 70% of the major claims were either the last sentence of the introduction or in the first sentence of conclusions, while 67% of key subsidiary claims show up in the first or last sentence of the middle paragraphs.

Our results also suggested that we can incorporate non-semantic features into deep models to help the model learn, especially these non-semantic features can not be captured by the word embedding features.

6.3 Discourse Indicator features

Interestingly, the performance of linear models was not improved after adding the discourse features, and DAG model’s performance was improved a little. When we examine the data more closely we see that one possible reason is the current discourse indicator list provided in [27] does not cover all the cases in the PE. We identified more discourse indicators that are not included in the list, such as thesis indicators of “it is believed that”, “to summarise”, “in short”, “it is undeniable”, and “I admit that” and forward indicators of “based on the above discussion”. We will address this problem in our future work.

We also experimented with incorporating discourse features by category. We ran another set of experiments based on the same model parameters setting as above. Below Table 3 shows the results.

Features	LSTMs		DAG-LSTMs	
	Pos-Dis	Dis	Pos-Dis	Dis
Major Claim	.843*	.662*	.859*	.675*
Claim	.666	.475*	.659	.506*
Premise	.899	.817	.894	.794
Macro-F1	.803*	.651*	.804*	.659*

Table 3: Results for incorporating discourse indicators as annotation types for Linear-LSTMs and DAG-LSTMs.* means improvement over the results that show in Table 2.

After incorporating discourse indicator features by category, the model’s performance was improved. In Table 3, * indicates the improvement over the results from n-gram discourse features. Both the linear and DAG models yield slightly better results on major claim and claim components, especially the major claim. Deeply looking at the results, some major claims were misclassified as claims before, which were correctly predicted here. The reason could be that when we consider the discourse indicators by category, we only have five features. For each feature, we have sufficient training examples for it. In fact, the thesis, first-person, forward, rebuttal, and backward indicators show up 701, 1535, 968, 719, and 1769 in the total data. Thus, it is easier for the models to capture the discourse features. However, when we considered them in the n-gram form, we have more than 100 of them. The number of them shows up in the ACs are much less than above. And some of them only show up once in the entire data, such as thesis indicators of “all things considered” and backward indicator of “is due to the fact that”, which prohibits the models learning useful information.

Overall, the discourse indicator features did not improve the model’s performance massively, which indicates that deep models with pre-trained embeddings already capture the semantic information. Thus, adding discourse indicator features does not help as much as position features on PE dataset.

6.4 Linear-LSTMs vs DAG-LSTMs

When adding both classes of features, the linear and DAG models yielded similar results for their macro-F1 score. However, the linear models outperformed the DAG models with the position features alone, and the DAG models utilized the discourse indicator features better in both the Table 2 and Table 3. One possible explanation is that when we concatenated the feature vectors on the last hidden output of linear models, the models are not able to learn the interactions between the discourse indicators and surrounding words. But the DAG models can learn those interactions by merging the hidden annotation states with current hidden states, and the current states contain the semantic information from all previous tokens. For example, for the DAG-input shown in Figure 1, we use the index of the DAG input to refer the time step that the LSTM unit processes the hidden state. At time step 15 of the forward training, we first merge the hidden output of state 10 and state 14, and then pass the merged hidden state as the hidden input of state 15. In this way, the DAG models consider both semantic meaning of all previous tokens and the discourse feature of “I firmly believe that”, and pass that information to the next hidden state. These results imply that DAG-models tend to utilize the semantic features better as they can learn the interaction between the features and tokens. However, they might not perform very well when we consider non-semantic features, such as the position features used here. One possible ap-

proach to address this problem is to combine two proposed methods to incorporate features. We can use DAG models to incorporate discourse indicator features and then concatenate the one-hot position feature vectors on the final hidden states for prediction.

7. CONCLUSIONS

In this work, we experimented with two approaches to combine feature engineering with deep models: linear-Bi-LSTMs with feature vectors concatenated on the hidden output and DAG-Bi-LSTMs. Our results show that both deep models could benefit from task-specific features, as both of them outperformed traditional models with heavy feature engineering and deep models with no task-specific features. We also show that the linear models handle the position feature better, and that the DAG models utilize the semantic features better since the linear models can not learn the interaction between discourse features and tokens. And finally we show that the deep models benefit more from position features than discourse indicator features on the PE dataset. Our results imply that when we apply the deep learning models to classify ACs, we could consider utilizing some task-specific features to guide the model learning.

This work can serve as a basis for the development of structurally-aware support platforms for reading and writing. This can include automated essay grading systems that detect and evaluate structural deficiencies as well as writing tutors that scaffold the construction of coherent essays or identify structural issues. As discussed in Section 1, current automated grading systems suffer from the lack of reliable auto-extraction mechanisms with most still relying on traditional ML models that use heavy feature engineering to function. Such work is costly and time consuming to develop and may not always generalize to other essay types. Our work addresses this problem by showing that lightweight features and off the shelf methods can outperform those methods. At the same time our work also showed that while traditional machine learning models are costly and deep learning models are sensitive to small datasets, as discussed by [8, 31], this limitation too can be addressed through the use of lightweight feature work to guide the deep models. By addressing these two problems we have shown a path for developing robust argument detection mechanisms for automated educational platforms using novel deep learning approaches a path that can lead to substantive improvements for students and educators.

8. FUTURE WORK

These preliminary results serve as a basis for our ongoing research, in which we are building an end-to-end model with feature engineering to address all three sub-tasks for argument structure extraction. For that work we will frame this task as sequence tagging problems. We propose to use linear-LSTM and DAG-LSTM based models with task-specific features to address EAS. We estimate that incorporating the task-specific features into end-to-end models can improve the model's performance compared to the deep models based on general word embedding [6].

In future work, we will also consider experimenting these two approaches on different argumentation datasets, and compare the results with fine-tuning SOTA language models (e.g. BERT [5], T5 [20]).

ABSTRACT

Accurately predicting which students are best suited for graduate programs is beneficial to both students and colleges. In this paper, we propose a quantitative machine learning approach to predict an applicant's potential performance in the graduate program. Our work is based on a real world dataset consisting of MS in CS students in the College of Computer and Information Science program at Northeastern University. We address two challenges associated with our task: subjectivity in the data due to change of admission committee membership from year to year and the shortage of training data. Our experimental results demonstrate an effective predictive model that could serve as a Focus of Attention (FOA) tool for an admission committee.

support vector machine (SVM), semi-supervised learning, learning using privileged information (LUPI), multi-task learning, Educational Data Mining (EDM), business intelligence in education

1. INTRODUCTION

Master's education is the fastest growing and largest component of the graduate enterprise in the United States. According to the 2016 joint survey conducted by the CGS (Council of Graduate Schools) and ETS (Educational Testing Service) [4], first-time enrollment in U.S. graduate programs reached a record high total of 506,927 students in Fall 2015. Because of the rise in applicants, the admissions process may become increasingly tedious and challenging. The ETS has established standardized tests (such as the GRE) to help evaluate applicants' quantitative, reading, and writing skills, but these scores alone are far from indicative of success-

ful students. Although applicants' previous achievements can demonstrate excellence, students with high GPAs from prestigious universities do not always excel in their graduate studies.

In this paper, we take a quantitative machine learning approach to predict the outlook of applicants' graduate studies based on features extracted from their application materials. The training data for our model are empirically admitted students with their performance measures in the graduate program. In particular, we have a real world dataset from Northeastern University's MS in Computer Science (MSCS) program, consisting of MS students from 2009 to 2012. We use a student's overall GPA in the MSCS program as his/her performance measure. Our model aims to identify the top 20% and bottom 20% performing students respectively (see details in Section 4.1).

Two challenges arise when learning with this data. First, the data involves the admission committee's (possibly subjective) evaluation. Specifically, some members of the committee may be biased in weighing a particular set of standards (e.g., GRE scores), while others may be in favor of different measures. This issue is particularly acute when the admission committee/policy changes from year to year. As a result, it can be difficult to form an accurate predictor directly from the entire dataset. Another challenge is the limitation of the training data. We have a total of 454 labeled training samples (all admitted students) from 2009 to 2012. On the other hand, we have over 2000 applications that are either rejected (i.e., not admitted) or declined (i.e., admitted but not enrolled), which can serve as an unlabeled auxiliary dataset. Our conjecture is that building a semi-supervised model leveraging the large set of unlabeled data may lead to a superior performance compared to using the labeled data alone.

Our model is inspired by two existing frameworks: SVM+ [12] and S3VM [3]. SVM+ is a variant of SVM which addresses the issue of heterogeneous data. Specifically, SVM+ implicitly establishes a different hyper-plane for each data subgroup by modifying a standard SVM's objective function and constraints. S3VM is a semi-supervised version of

Yijun Zhao, Bryan Lackaye, Jennifer Dy and Carla Brodley "A Quantitative Machine Learning Approach to Master Students Admission for Professional Institutions" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 538 - 544

SVM which learns a classifier using both labeled and unlabeled data. Our contribution is a new variant of SVM that unifies the advantages of both S3VM and SVM+. Our new model, which we name S3VM+, addresses the admission biases in the labeled data and utilizes unlabeled applicants' data simultaneously. S3VM+ can be applied to any domain for which the data may have clearly defined subgroups (e.g., privileged domain knowledge) and a large amount of unlabeled data.

An additional motivation of our research was to validate our hypothesis of whether we could predict student success based only on quantitative measures and, thus, remove the subjectivity of the committee reading the recommendation letters and statement of purpose. If successful, such a model will not only lead to a better selected student body, but also help to manage growing enrollments. Our experimental results (see Section 4 for details) demonstrate that, with our new model, we can achieve an effective yet imperfect prediction. Thus, in practice, our model could serve as a Focus of Attention (FOA) tool for the admission committees.

The rest of the paper is organized as follows: in Section 2, we present the related work in predicting students' performance in the education domain. In Section 3, we give brief introductions to S3VM and SVM+ and present our model S3VM+ in detail. We demonstrate the efficacy of our model in Section 4 by comparing its performance to those three existing models. Finally, we conclude in Section 5.

2. RELATED WORK

Most EDM studies focus on predicting students' academic performance after they have been admitted to the college or program. For example, Lepp et al. investigated the relationship between cell phone use and academic performance in a sample of US college students [8]. Delen applied machine learning techniques for student retention management [6]. Ioanna et al. presented a dropout prediction in e-learning courses using machine learning techniques [10]. Nevertheless, another important aspect of educational research is selecting the best fitting students at admission time, which has not been widely addressed in past literature.

The most closely related work to our paper is the admissions research conducted by the University of Texas at Austin (UT Austin) for their graduate admission program [14], driven in part by their need to manage growing application numbers. In their work, the authors applied logistic regression (LR) to help the admission committee identify weak candidates who will likely be rejected and exceptionally strong candidates who will likely be admitted. Our work bears a similar mission but is different in three aspects. First, the UT Austin research includes credentials such as recommendation letters and statement of purpose, whereas our work strives to build a purely quantitative model relying only on non-subjective measures. Second, the recommendations made by UT Austin's algorithm are based on an applicant's likelihood of admission, whereas our model aims to predict the future performance of the applicants in the graduate program. Last, our model addresses human subjectivity in admission decisions. The contribution of our paper is a quantitative machine learning model to predict a candidate's future performance at admission time.

3. INTEGRATING SEMI-SUPERVISED SVM WITH DOMAIN KNOWLEDGE

We choose our model based on the characteristics of our dataset and particular challenges involved in our task. In particular, we choose SVM and two existing frameworks: S3VM [3] and SVM+ [12]), as our baseline models. Our proposed model is a new variant of SVM, which is inspired by S3VM and SVM+. We first give brief introductions to S3VM and SVM+. We then describe our new model in detail in Section 3.3.

3.1 S3VM (Semi-Supervised SVM)

S3VM is semi-supervised SVM proposed by [3]. The model is learned using a mixture of labeled data (the training set) and unlabeled data (the auxiliary set). The objective is to assign class labels to the auxiliary set such that the "best" support vector machine (SVM) is constructed. In particular, given a labeled dataset $L = \{x_1, x_2, \dots, x_l\}$ and an unlabeled auxiliary dataset $U = \{x_{l+1}, x_{l+2}, \dots, x_{l+k}\}$, S3VM learns a classifier from both L and U using overall risk minimization (ORM) posed by Vapnik [13] (Chapter 10). Starting with the standard SVM formulation, S3VM adds two constraints for each data point in the auxiliary set U . One constraint calculates the misclassification error as if the point were placed in class 1, and the other constraint calculates the misclassification error as if the point were placed in class -1. The objective function calculates the minimum of the two possible misclassification errors. The final membership assignments of the instances in U correspond to the ones that result in a minimum total sum of slacks across all instances in the training set. Specifically, we have:

$$\min_{w, b, \eta, \xi, z} \quad \frac{1}{2} \|w\|^2 + C \left[\sum_{i=1}^l \eta_i + \sum_{j=l+1}^{l+k} \min(\xi_j, z_j) \right] \quad (1)$$

subject to

$$\begin{aligned} y_i(w \cdot x_i + b) + \eta_i &\geq 1 & \eta_i &\geq 0 & i &= 1, \dots, l \\ w \cdot x_j + b + \xi_j &\geq 1 & \xi_j &\geq 0 & j &= l+1, \dots, l+k \\ -(w \cdot x_j + b) + z_j &\geq 1 & z_j &\geq 0 & j &= l+1, \dots, l+k \end{aligned}$$

where C is the trade-off between maximizing the margin and total violations. η_i 's are the slacks for the labeled data, and ξ_j 's and z_j 's are the slacks for the unlabeled data hypothetically assigned to the positive and negative classes respectively.

Equation (1) can be solved using mixed integer programming by applying the "large integer M " technique. The idea is to introduce a constant integer $M > 0$ and a decision variable $d_j \in \{0, 1\}$ for each point x_j in the auxiliary set U . d_j indicates the class membership of x_j . If $d_j = 1$, then the point is in class 1 and if $d_j = 0$, then the point is in class -1. The integer M is chosen sufficiently large such that if $d_j = 0$ then $\xi_j = 0$ is feasible for any optimal w and b . Likewise if $d_j = 1$, then $z_j = 0$. In other words, ξ_j and z_j can have at most one non-zero value no matter what class x_i belongs to. Consequently, we could replace the $\min(\xi_j, z_j)$ in Equation (1) by

$(\xi_j + z_j)$. This results in the following formulation:

$$\min_{w, b, \eta, \xi, z} \quad \frac{1}{2} \|w\|^2 + C \left[\sum_{i=1}^l \eta_i + \sum_{j=l+1}^{l+k} (\xi_j + z_j) \right] \quad (2)$$

subject to

$$\begin{aligned} y_i(w \cdot x_i + b) + \eta_i &\geq 1 \\ \eta_i &\geq 0, \quad i = 1, \dots, l \\ w \cdot x_j + b + \xi_j + M(1 - d_j) &\geq 1 \\ -(w \cdot x_j + b) + z_j + Md_j &\geq 1 \\ \xi_j &\geq 0, \quad z_j \geq 0, \\ j &= l+1, \dots, l+k, \quad d_j \in \{0, 1\} \end{aligned}$$

The solution to Equation (2) can be found using mixed integer programming products. In our experiment, we used CVX [1] and Gurobi [2] optimizers. Same as a standard SVM, S3VM classifies a new instance x^* using $\text{sign}(w \cdot x + b)$.

3.2 SVM+

Vapnik and Vashist [12] introduced SVM+, which is a variant of SVM that addresses the issue of learning with heterogeneous data. In their model, the authors developed a new paradigm to learn using privileged information (LUPI). The objective of SVM+ is to take advantage of additional domain knowledge, and in particular data subgroups that may arise from different sources or due to labeling biases.

Suppose the training data has $t > 1$ groups. We follow the notation in [9] and denote the indices of group r by

$$T_r = \{i_{n_1}, \dots, i_{n_r}\}, \quad r = 1, \dots, t$$

All training samples can then be represented as:

$$\{\{X_r, Y_r\}, \quad r = 1, \dots, t\}$$

where $\{X_r, Y_r\} = \{(x_{r_1}, y_{r_1}), \dots, (x_{r_{n_r}}, y_{r_{n_r}})\}$. To incorporate the group information, SVM+ defines the slacks inside each group by a unique *correcting function*:

$$\xi_i = \xi_r(x_i) = \phi_r(x_i, w_r), \quad i \in T_r, \quad r = 1, \dots, t$$

Specifically, the correcting functions are defined as:

$$\xi_r(x_i) = w_r \cdot x_i + d_r, \quad i \in T_r, \quad r = 1, \dots, t$$

Compared to a standard SVM, S3VM uses slack variables that are restricted by the correcting functions, and the correcting functions capture additional information about the data. Note that all of the data is used to construct the decision hyperplane. The group information is only used to fine tune the slack variables. Formally, the objective function for SVM+ is formulated as follows:

$$\min_{w, b, w_1, w_2, w_r, d_1, d_2, d_r} \quad \frac{1}{2} \|w\|^2 + \frac{\gamma}{2} \sum_{r=1}^t \|w_r\|^2 + C \sum_{r=1}^t \sum_{i \in T_r} \xi_i^r \quad (3)$$

subject to:

$$\begin{aligned} y_i(w \cdot x_i + b) + \xi_i^r &\geq 1 \\ \xi_i^r(x_i) &= w_r \cdot x_i + d_r \\ \xi_i^r &\geq 0, \quad i \in T_r, \quad r = 1, \dots, t \end{aligned}$$

Parameter γ adjusts the relative weight between $\|w\|^2$ and the $\|w_r\|^2$'s. C is the trade-off between maximizing the margin and total violations.

Liang and Cherkassky [9] further extended the SVM+ approach to multi-task learning. In the SVM+MTL [9] framework, the data is partitioned into groups using privileged information similar to the SVM+ model. However, instead of making a correcting function for the slack variables, their model establishes a unique correcting function (i.e., a hyper-plane) for each group in addition to a shared common hyper-plane. In other words, the decision function for group $r = 1, \dots, t$ is as follows:

$$f_r(x) = (w \cdot x + b) + (w_r \cdot x + d_r)$$

where w, b are the parameters for the common hyper-plane and w_r, d_r are the parameters for the correcting function for group r . The corresponding formulation of the quadratic optimization problem is as follows:

$$\min_{w, b, w_1, w_2, w_r, d_1, d_2, d_r} \quad \frac{1}{2} \|w\|^2 + \frac{\gamma}{2} \sum_{r=1}^t \|w_r\|^2 + C \sum_{r=1}^t \sum_{i \in T_r} \xi_i^r \quad (4)$$

subject to

$$\begin{aligned} y_i[(w \cdot x_i + b) + (w_r \cdot x_i + d_r)] + \xi_i^r &\geq 1 \\ \xi_i^r &\geq 0 \quad i \in T_r, \quad r = 1, \dots, t \end{aligned}$$

SVM+MTL is an adaptation of SVM+ for solving MTL problems. In our experiment, we applied the SVM+MTL framework because it provides more flexibility to learn a different decision plane for each year's student data.

For SVM+MTL, predicting the class label for a new given instance x^* is not straightforward because its decision function requires a group-dependent correcting function, and we do not know the group membership of test instances. To resolve this problem, we predict the label for x^* in each group and perform a majority vote over all predicted labels. Specifically, a test instance x^* will be predicted in each group as follows:

$$f_r(x^*) = \text{sign}[(w \cdot x^* + b) + (w_r \cdot x^* + d_r)]$$

where $r = 1, \dots, t$ are the bias groups, and w, b, w_r 's and d_r 's are learned model parameters. The class membership for x^* is determined by a majority vote over $f_r(x^*)$'s.

3.3 S3VM+

Our new model, S3VM+ leverages the unlabeled data and addresses the biases in the training data simultaneously. In particular, we train our model with a labeled dataset and an unlabeled auxiliary dataset. Furthermore, our data is partitioned into yearly groups because of the admissions committee changes from year to year and thus may have different biases. For the labeled dataset, we incorporate the grouping information by establishing a correcting function for each group (constraints (a) and (b) in Equation (5)).

For the unlabeled data, we introduce two slack variables ξ_i and z_i for each data point x_i representing the slacks of placing x_i in the positive class and negative classes respectively. The objective function for S3VM+ takes the minimum of the two slacks for each unlabeled instance and minimizes the total sum of slacks across all training instances. We apply the "large integer M " technique (see Section 3.1 for details) and convert the constraint with a minimization function to two constraints over linear functions. Because both labeled and

unlabeled data are grouped by academic year, we apply the same correcting functions used for the labeled data to each corresponding annual group of unlabeled data (constraints (c) to (f) in Equation (5)). Formally, the optimization problem for S3VM+ is formulated as follows:

$$\min_{w, b, w_1, w_2, w_r, d_1, d_2, d_r} \frac{1}{2} \|w\|^2 + \frac{\gamma}{2} \sum_{r=1}^t \|w_r\|^2 + C \left[\sum_{i=1}^l \eta_i^r + \sum_{j=l+1}^{l+k} (\xi_j^r + z_j^r) \right] \quad (5)$$

subject to

- (a) $y_i[(w \cdot x_i + b) + (w_r \cdot x_i + d_r)] + \eta_i^r \geq 1$
- (b) $\eta_i^r \geq 0 \quad i = 1, \dots, l$
- (c) $[w \cdot x_j + b + (w_r \cdot x_j + d_r)] + \xi_j^r + M(1 - d_j) \geq 1$
- (d) $\xi_j^r \geq 0 \quad j = l+1, \dots, l+k, \quad d_j \in \{0, 1\}$
- (e) $-[(w \cdot x_j + b) + (w_r \cdot x_j + d_r)] + z_j^r + Md_j \geq 1$
- (f) $z_j \geq 0 \quad j = l+1, \dots, l+k \quad d_j \in \{0, 1\}$

where C is the trade-off between maximizing the margin and total violations, and γ is the trade-off parameter between $\|w\|^2$ and the $\|w_r\|^2$'s. Note that constraints (a), (b) are for labeled instances and constraints (c) – (f) are for unlabeled instances.

To classify a new instance x^* , we follow the same approach as SVM+, which is to take a majority vote on class labels predicted by each group.

4. EXPERIMENTAL RESULTS

In this section, we first describe the process of constructing our training and testing dataset. We then discuss the methods we used to conduct our experiments in Section 4.2. We present our analysis of our experiments in Section 4.3.

4.1 Constructing the Training and Test Data

We have a real world dataset consisting of students from the MSCS program at Northeastern University. Table 1 presents the features we collected from students' applications for our experiment. Feature 1 contains the students' undergraduate GPAs adjusted according to each individual university's grading scale. For example, a 3.5 out of 5 and a 7 out of 10 would result in the same value. Feature 10 contains self-reported values representing the maximum number of lines of programming written by the student prior to joining the MS program. Feature 12 contains the rankings of the undergraduate institutions where the students obtained their bachelor's degrees. We classified the rankings into 4 categories with 1 being the most prestigious. The classification was performed manually according to the Best Global Universities list published by US News and World Report. The rest of the features are standardized test scores. Both the GRE and TOEFL had two versions of tests during 2009 - 2012 which use different scoring scales. Both of these tests are converted to their new versions of scoring scales using conversion tables provided by the ETS [4].

As mentioned in Section 1, our task is to identify successful candidates at the point of admission. One measure of success is MS-GPA in the MS program (as distinct from the input feature 1 "Undergraduate GPA"). Indeed, a cumulative MS-GPA is the most widely used measure for students'

Table 1: Features Collected for Training

1	Undergraduate GPA
2	GRE Verbal
3	GRE Quantitative
4	GRE Analytical Writing
5	TOEFL Total
6	TOEFL Reading
7	TOEFL Listening
8	TOEFL Speaking
9	TOEFL Writing
10	Max # of Lines of Code Written
11	Bachelor's Degree in EECS (Yes/No)
12	Undergraduate School Ranking

Table 2: Student Data Statistics

Year	Total	Top 20%	Bottom 20%	Aux. Data
2009	37	7	7	431
2010	89	18	17	503
2011	132	28	27	705
2012	196	51	42	948

academic performance [11]. The labels in our training data are determined by the training instances' percentiles in the overall MS-GPAs. Specifically, the top and bottom 20% students are labeled with class 1 and -1 respectively. The number 20% was intuitively chosen as an measure which sets the individuals apart from the average students.

Note that we did not use a midpoint MS-GPA as a cutoff to separate the positive and negative classes, in order to reduce the label noise. In particular, instances close to the average GPA are harder to categorize as good or bad students.¹ Another intuitive approach is to define two hard MS-GPA thresholds for good versus bad performances, i.e., to have a MS-GPA above an upper threshold (e.g., > 3.8) for good students, and below a bottom threshold (e.g., < 3) for bad students. A further investigation reveals that this approach is less effective for the following reason: different instructors have different grading policies due to the nature of the courses. For some fundamental courses, an 'A' means you are in the top 30% of a class, while for some other advanced courses, an 'A' means you are in the top 10% of a class. Even for the same course in the same year with different sections, the instructors may choose to cooperate exams/grading or not. Because students have different instructors and/or even take different courses, hard cutoffs are not an accurate reflection of a student's abilities.

Having stated this, on the other hand, if a student performs consistently in the top 20% in each class, this student will be among the top 20th percentile of the entire MS-GPA spectrum. The same can be said for those that perform consistently in the bottom 20th percentile. Identifying the factors that lead to this consistent success or underperformance are of greatest interest to this research. Therefore, we used relative measures to label our positive and negative training samples. For comparison purposes, we report our experimental results on both relative and hard cutoffs in Tables 5 and 6 respectively.

¹We did experiment with splitting the two classes using the mean value of all MS-GPAs and the performance was not satisfactory as expected.

Table 3: Prediction Using 1Y Data

Train	Test	Top20% MS-GPA	Bot20% MS-GPA	Overall
2009	2010	0.72	0.59	0.66
2010	2011	0.64	0.70	0.67
2011	2012	0.65	0.76	0.70

Table 4: Predicting Using 10-fold Cross Validation

Model \ MS-GPA%	Test Accuracy			Training Accuracy		
	Top20	Bot20	Overall	Top20	Bot20	Overall
2009 - 2011	0.70	0.71	0.71	0.79	0.79	0.79
2009 - 2012	0.74	0.72	0.73	0.84	0.75	0.79

Table 2 summarizes the distribution of students from 2009 to 2012. Column “Total” is the total number of students enrolled in the corresponding year. Columns “Top 20% MS-GPA” and “Bottom 20% MS-GPA” are the total number of students in the top and bottom 20th percentile among their peers measured by the cumulative MS-GPAs. There is not an equal number of positive and negative instances for each year because there are multiple students with same MS-GPA.

Both SVM+ and our model S3VM+ make use of an unlabeled auxiliary dataset. We collect the application data of rejected (i.e., not admitted) and declined (i.e., admitted but not enrolled) applicants as the auxiliary data. These data contain the same features as the labeled data, and the size distribution of auxiliary data from 2009 to 2012 is presented in the last column of Table 2. Our training data are all labeled and unlabeled instances from 2009 to 2011, and our test data are labeled instances from 2012.

4.2 Experimental Method

We are interested in identifying the top and bottom 20% of candidates from an application pool based on the performance of the admitted students. Our first goal is to confirm our conjecture that there are biases in admission decisions from year to year. To this end, we conducted two experiments. The first experiment is to use the previous year’s data to predict the current year’s performance using a standard SVM. For example, we would use class 2009’s data to predict class 2010’s performance, and class 2010’s data to predict class 2011’s performance. Table 3 presents the prediction accuracies for each year. We observe that, for 2010, the top 20% of students are easier to predict than the bottom 20%, whereas for 2011 to 2012, the situation is reversed. This lack of consistency and the low overall accuracies (up to 70%) suggest that there is no strong correlation of predictive patterns from year to year. Our second experiment is to apply a standard 10-fold cross validation on two datasets: all data from 2009 to 2011 and all data from 2009 to 2012. Because 2012 added a significant amount (89%) of instances, we would expect a noticeable increase in both the training and test accuracies if the data across different years conform to the same distribution. Table 4 summarizes the results of this experiment. We observe only a marginal improvement in overall test accuracy after adding instances from 2012 and, more importantly, the overall fit of the data remains the same (79%). From these two experiments, we conclude

Table 5: Performance Comparison with Relative Cutoffs

Model \ MS-GPA%	Test Accuracy			Training Accuracy		
	Top20	Bot20	Overall	Top20	Bot20	Overall
SVM	0.73	0.71	0.72	0.79	0.80	0.79
S3VM	0.75	0.74	0.74	0.81	0.82	0.81
SVM+	0.77	0.70	0.74	0.92	0.84	0.88
S3VM+	0.82	0.72	0.77	0.95	0.89	0.92

Table 6: Performance Comparison with Hard Cutoffs

Model \ MS-GPA	Test Accuracy			Training Accuracy		
	>3.8	<3.4	Overall	>3.8	<3.4	Overall
SVM	0.65	0.69	0.66	0.73	0.75	0.74
S3VM	0.72	0.65	0.70	0.83	0.70	0.77
SVM+	0.75	0.64	0.71	0.92	0.75	0.84
S3VM+	0.77	0.67	0.74	0.93	0.80	0.87

that data across different academic years have different distributions. We believe this year to year bias is due to the change in the membership of the admission committee.

In light of above learned information, we partitioned the data by academic year and use them as the privileged groups in SVM+ and S3VM+. We take the union of labeled data from 2009 to 2011 as our labeled training data. The auxiliary dataset is formed as the union of the corresponding auxiliary data from 2009 to 2011. We test and compare the performance of the four models (SVM, S3VM, SVM+, S3VM+) in predicting labeled instances in 2012.

The hyper-parameters are the trade-off constant C for all four models and γ for SVM+ and S3VM+. We perform 10-fold cross validation and grid search on the training data to select the hyper-parameters. We first use a coarse grid $\{0.01, 10, 1000\}$ for C and refine the candidates after the initial search. The final list for C is $\{1, 10, 100\}$. Following a similar procedure, our final search list for γ is $\{0.01, 1, 100\}$. After the best hyper-parameters are selected, we train the corresponding model one more time using the entire training data and then apply the learned model to the test data and measure its performance. We report both training and test accuracies in Table 5.

4.3 Analysis on Performance Measures

Table 5 displays the main results of our experiment. First, we observe that the test accuracies for SVM on the positive and negative classes are more balanced compared to the results in Table 3. There is also an improvement in the overall performance for SVM. This can be explained by the increased amount of training data used in our Table 5 experiment.

Second, we conclude that all three variants of SVM (S3VM, SVM+, S3VM+) are superior to standard SVM. Using SVM as a baseline measure:

- S3VM improved slightly on the accuracies of both positive and negative classes, which suggests that using auxiliary data has a positive impact on identifying both the good and bad students. This is consistent with the fact that the auxiliary data contain both de-

clined (i.e., admitted but not enrolled) and rejected (i.e., not admitted) applicants, which could improve the accuracy of positive and negative classes respectively.

- SVM+ demonstrated improvement on the positive side only, which indicates that the partition of bias groups by academic year is most effective in identifying the top students. One explanation for this could be that the top 20% of students are inherently different from year to year, while the bottom 20% of students remain similar. Or that a particular admissions committee has biases about how to recognize a strong student.
- Our model S3VM+ has a noticeable advantage among all models in predicting the positive class: 83% versus 73% (SVM), 75% (S3VM) and 77% (SVM+). In light of the construction of S3VM+, one could conclude that adding auxiliary data to each partition group further enhances the power of identifying top students. On the other hand, because grouping does not have a significant impact on identifying bottom students (as demonstrated by SVM+), S3VM+ would only result in a limited gain for the negative class.

Lastly, from the training accuracies presented in Table 5, we observe a significantly better fit of the training data using our model S3VM+. In particular, 95% versus 92% (SVM+), 81% (S3VM), 79% (SVM) accuracies for the positive class and 89% versus 84% (SVM+), 82% (S3VM) and 80% (SVM) accuracies for the negative class. Compared to the standard SVM, S3VM improved training accuracies evenly on both classes, and SVM+ and S3VM+ demonstrated more significant gains on the positive class, which is consistent with what we observed in the test data.

4.4 Labeling Strategy: Relative v.s. Absolute

Recall that in Section 4.1, we discussed our choice of labeling the top 20% and bottom 20% of students with respect to their MS-GPAs as our two classes. We explained our rationale of using relative rather than hard cutoffs to label our data. We confirm this conjecture in Table 6, where we show the results of an experiment using $\text{MS-GPA} > 3.8$ for the top students and $\text{MS-GPA} < 3.4$ for the other. In the table we see that for all four methods, the overall accuracies are lower than in Table 5.

4.5 Analysis on Weight Vectors

Because we utilized a linear SVM and its variants, we found it interesting to investigate the ranking and magnitude of each individual feature in the weight vectors produced by each model. Table 7 presents the ranking of w_i 's in the weight vectors (w 's) of four models. Figure 1 displays the weights of individual features across four models using their magnitudes. In order to make a meaningful comparison, each weight vector $w = \{w_1, w_2, \dots, w_{12}\}$ is scaled by the maximum absolute value of its components. Thus, the weight for the most important feature is either 1 or -1. Note that, for SVM+ and S3VM+, we display the shared hyper-plane vector w without the correcting functions for each group.

From Table 7, we observe that all models except standard SVM suggest the same top two features: "GRE Quantitative" and "GRE Analytic Writing" scores. Furthermore,

Table 7: Weights Ranking Comparison

Model	R1	R2	R3	R4	R5	R6	R7	R8	R9	R10	R11	R12
SVM	w_1	w_{11}	w_4	w_{12}	w_3	w_9	w_7	w_2	w_6	w_8	w_5	w_{10}
S3VM	w_4	w_3	w_{11}	w_1	w_6	w_2	w_7	w_{10}	w_9	w_{12}	w_5	w_8
SVM+	w_3	w_4	w_9	w_2	w_{11}	w_1	w_7	w_5	w_8	w_{12}	w_6	w_{10}
S3VM+	w_3	w_4	w_{11}	w_2	w_9	w_7	w_1	w_{12}	w_5	w_8	w_{10}	w_6

Figure 1: Weights Distribution Over 12 Features Across Four Models

The weights are normalized using $w = \frac{w}{\max_{1 \leq i \leq 12} \{|w_i|\}}$

SVM+ and S3VM+ overlapped in their top five features but with a different ranking order.

From Figure 1, we conclude that the most important features are 1 ("Undergraduate GPA"), 2 ("GRE Verbal"), 3 ("GRE Quantitative"), 4 ("GRE Analytical Writing") and 11 ("Bachelor's Degree in EECS (Yes/No)"). A closer examination reveals that SVM relies mostly on three features (1, 4, and 11). S3VM has significantly large weights on two additional features, 6 ("TOEFL Reading") and 7 ("TOEFL Listening"), on top of the five features listed above. SVM+ and S3VM+ made use of one additional feature which is 9 ("TOEFL Writing").

5. CONCLUSIONS

In this paper, we applied a quantitative machine learning approach to predict candidates' potential academic performances based on information from their applications. We built our model using empirically admitted students with their cumulative GPAs as performance measures and tested our model's efficacy for the incoming students. Throughout our experiments, we found a unique challenge associated with our task, which is different data distributions across the academic years due to biases arising from changing membership of the admissions committee. We addressed this issue with the Learning Using Privileged Information (LUPI) framework. We further handled the limited training data issue by employing a semi-supervised version of SVM to utilize the large amount of unlabeled data (i.e., the rejected/declined applications). Our resulting model, S3VM+, is a novel variant of SVM that addresses subjectivity and lack of labeled data simultaneously. Our experimental results demonstrate a significant gain of our model compared to three existing models in standard literature (i.e., standard SVM, S3VM, and SVM+). Although we based our work on a two-year master's program, our model is easily extensible to similar tasks such as college or pre-school admissions. Our model can also be applied to other real world situations in which data may have clearly defined biased subgroups and a large amount of unlabeled data.

ABSTRACT

There have been discussions on where to invest the budget allocated to education. Most politicians want to invest in the schools' infrastructure, but is that the most efficient policy for spending? This paper presents analyses to help clarify that. It integrates the most recent data sources (2018) on the secondary students' assessment (ENEM), the School Census and the Teachers' Census and consolidates all microdata to the school level, making them features of the schools. These features are then grouped into three types: infrastructure, human education and socio-economic aspects. Then the features from each group are applied in logistic regression predictive models both isolate and collectively. In a 10-fold cross-validation comparison with the area under the ROC curve as metric. The experimental results show that infrastructure is significantly less influential than the other features. Further research needs to consider investment costs and time to produce effect on school performance.

Keywords

School quality assessment, Educational decision support system, Educational Data Mining, Domain-Driven Data Mining, Educational budget allocation

1. INTRODUCTION

International comparison of students' performance among countries by the Programme for International Student Assessment (PISA) has yielded strategic discussions in international education policies. The PISA, sponsored by Economic Co-operation and Development (OCDE), aims at assessing and providing a global perspective on secondary education (15-year-old pupils) across countries of the world [16].

Following the international efforts, the local governments have been concerned with standardized tests themselves, aiming at the assessment of students as much as at monitoring the quality of the educational system [1]. In Brazil, the National Institute for Educational Studies (Instituto Na-

cional de Estudos e Pesquisas Educacionais – INEP) produces the annual School Census which is a survey of the schools for secondary education in the country and the National Secondary School Exam (Exame Nacional do Ensino Médio – ENEM) that evaluates student performance at end of secondary education.

In 2009, ENEM became a mechanism for students' admission to higher education in public universities. That improved the quality of the information collected. Added to the technical knowledge of each student, ENEM also captures their socio-economic-cultural (SEC) information [2]. The integration of this information with the School Census data has become a relevant source of data for scientific studies and enables the Federal Government to define and validate public policies for Brazilian education [30]. However, secondary education is under jurisdiction of the constituent states of the federation, not the national government. Thus, despite the importance of the federal government role, there is considerable variation among the states in curriculum, teacher training, budget policies and other issues [10].

Many factors can influence the performance of the students. Studies have shown that school inputs, students' SEC background, parents' education are correlated with student achievement [13, 7, 12]. In Brazil, according to the last school census available for this research (2018), 42% of the secondary public schools still lack Basic Infrastructure Level. The definition of the quality of the levels was performed by Neto [26] being the Basic Level the second lowest of four levels which includes features like having a management room with computer and printer for administrative work only. This scenario makes Brazilian politicians focus most of their educational bills and budget allocations on improving school infrastructure [19].

Despite the importance of providing infrastructure to schools, it is common for politicians to invest in infrastructure such as computer labs, tablets, TVs etc. even for schools that have not reached the basic level yet. This paper does not discuss pedagogical issues related to infrastructure; just tries to help policymakers and education-related institutions on how to invest their budget to comply with both regulations and education quality goals in a long-run plan to secondary public education.

This paper presents experiments in a Domain-Driven Data Mining (DM) approach that assesses the quality of secondary

Paulo Jorge L. Adeodato and Rogerio Luiz C. S. Filho "Where to aim? Factors that influence the performance of Brazilian secondary schools" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 545 - 549

schools in Brazil. The results show that the infrastructure predictors are less relevant than SEC and educational predictors at a 5% significance level. Experiments were carried out on the most recent data available (2018) with logistic regression models in a 10-fold cross-validation setting.

The paper is organized in 4 more sections. Section 2 presents the data sources and preprocessing. Section 3 describes the experimental project to elucidate the most influential group of features for predicting good students. Section 4 presents the results and discusses its impacts. And Section 5 presents the conclusions, difficulties found and suggestions for future work.

2. DATA SOURCES AND PREPROCESSING

This research has used two official public databases: Microdata from the National Secondary School Exam 2017 and 2018 containing the students SEC information and their grades on the test at the end of secondary education, and the School Census 2018 [2] detailing the conditions of the schools, from physical infrastructure to faculty information. The 2017 ENEM database was only used as an independent statistical sample to apply the process of granularity transformation described in Subsection 2.4. These databases refer to over 5 millions of students of 32,000 secondary schools across the country, but this paper will focus only on public (free) schools.

2.1 The Universe of Schools (Scope)

This research attempts to help policymakers optimize the budget allocation in order to improve Brazilian Secondary Schools. That does override the priority of the 42% of public secondary that have only an elementary infrastructure (just classrooms, electric energy, sanitation and piped water). A few schools (0.7%) were discarded from the database for being below that level.

ENEM is a democratic exam that any person can sit. That makes it necessary to apply some selection filters in student grain: a) Students who have no school assigned, are just training or are not in the last secondary school year (74%), b) students who do not follow a regular curriculum (2.5%) and c) foreign students (0.02%). The remaining 680,583 students were considered. To eliminate anomalies that could either divert from the goal or deteriorate the quality of the work, students who did not perform all the tests, including the essay, were also left out of the scope of this research.

Back to the school grain, for having critical mass, only schools with 10 or more students were selected, as established by INEP in the analyses. After this last filter, the total that remained in this research dropped to 14,579 secondary schools with 653,848 students which form the dataset used in this paper's experiments.

2.2 Problem Characterization and Goal Setting

In business, one of the most common decision strategies for selecting the eligible candidates for an action is ranking them according to a classification score and choosing those above a predefined threshold [17]. That is used in applications such as staff selection, fraud detection [6], and resources allocation

in public policies, for instance. This score is computed by either weighing a set of variables based on human-defined parameters or by applying a function learned by a classification algorithm from a set of data with binary labels as desired response, according to specific optimization criteria.

In some domains of application, several problems are ill-defined simply because stakeholders do not reach consensus on either method [29]. That is particularly true for education where experts and faculty do not agree even on the characterization of a good school or a good student. To circumvent these issues, we have adopted the systematic approach proposed by [3] to characterize this as a binary decision problem. Thus, the problem can be solved by machine learning algorithms based on the supervised learning paradigm with a data dependent strategy where each example is labeled as "good" or "bad" for binary decision making. That involves solving two scientific issues which represent controversial points in the application domain: (1) which metrics should be used as a ranking score for evaluating the quality of the school and (2) which threshold should be adopted as a criterion to define what would be a "good" school in the binary decision.

The ENEM [1] has been conceived to assess the quality of the Brazilian secondary schools based on their students' evaluation on the test. Despite arguments among experts on education, they have agreed that the performance of the students at the last year would represent their performance in the secondary school and also agreed that the mean student score would be the most relevant indicator of each school, as already done in previous studies [3, 30].

2.3 Binary Goal Definition

Once having defined the quality metrics, the most controversial point is to set the threshold to characterize what would be a "good" or "bad" school in the dichotomic objective. Once again, to circumvent the controversy and lack of consensus in the field on the issue and bring a higher level of abstraction that enables future comparison across years, regardless of the degree of difficulty of the exams, this study used statistics concepts for setting the threshold as recommended by [28]. Quartiles of the distributions not only are robust against extreme values (outliers) [21], but also can be a straightforward data dependent dichotomizing criterion of interest for the application domain. The upper quartile has already been successfully used as threshold [28] on a continuous goal variable for creating a binary target-variable. This paper has adopted that approach for converting the problem into a binary classification where the upper quartile represents the "good" schools.

2.4 Granularity Transformation

The granularity of the attributes is a fundamental concept and its diversity brings great complexity to research of this nature. How can one associate to each school its family income attribute from the distribution of family income of their students? How can one associate to each school its faculty education attribute from the distribution of faculty education of their teachers? These transformations represent a difficulty for teams without professionals specialized in developing data mining projects. This difficulty is due to both the sheer volume of data to be handled and the

need to use artificial intelligence to embed knowledge of experts in education in the transformation of the attributes for granularity change in a process coined Domain-Driven Data Mining (D3M)[23].

We considered and chose the Regression Granularity Transform (RGT) [4] as the most adequate approach for this research. It aims at maximizing the information gain towards the target class for categorical microdata present in Student and Teacher grains. Logistic Regression was the technique applied on the categorical attribute distribution having its histogram with the categories' relative frequencies as input. These transformations were learned from the previous year data (2017), to avoid having to discard data from the focus year of 2018. For numerical features, the average was the transformation adopted.

2.5 Preprocessing

Many factors affect the success of a data mining application. Data quality is among them [20]. Domain and data understanding allowed for the removal of irrelevant attributes (e.g. linked to elementary and fundamental schools and to other secondary school models that do not use the regular curriculum), attributes with a posteriori information and identification codes.

In the final data sample, just two binary features presented missing values, which were filled with "0", because they represented lack of that property. The categorical features that had the mode representing over 90% of the cases were removed.

For features with correlation higher than 0.8, only those with the highest semantic value for the domain were preserved. To reduce the influence of outliers and improve the quality of the Logistic Regression models, all numerical features were normalized using the α -winsorized values of the distribution ($\alpha/2 = 0.025$ at each tail) as their minimum and maximum.

3. EXPERIMENTAL PROJECT

The experiments were carried out using the Logistic Regression model in a 10-fold cross-validation setting. The features on school grain were partitioned into 3 different groups: 1) Infrastructure of schools, 2) SEC information of Students and 3) Level of Education of Parents and Teachers. The same held-out fold was used as test dataset for all groups and the models' performance on it was assessed by Area Under the Receiver Operating Characteristic (ROC) curve. ROC curve plots the true positive rate against the false positive rate, at all possible decision thresholds.

The goal is to experimentally compare the discriminant power of each group of predictors, focusing on groups 1 and 3, once that it is hard to produce any change in group 2 with educational policies. In one hand, it is widely known that features from group 3 are more influential than those of group 1, but it is hard for education policymakers to intervene on that due to limitations on either the country's economy or the Cash Transfer policies [22]. On the other hand, investment in features from group 1 has been the main focus of government, either by the insufficient conditions in some schools or because these investments have their effect more easily assessed. There are some studies in the literature on public

policies addressing teachers training and parents education [5, 8]. This paper aims at showing that the predictors of group 3 are more influential in predicting performance than those of group 1.

3.1 Performance analysis

Figure 1 shows the results for each test set in the 10-fold cross-validation process. In turns, one partition (fold) is separated for testing while the other 9 are used for training the model. The performance of the ROC curve at each fold, the average and the standard deviation across the 10 folds are the values reported. By comparing the results of groups 1 and 3, in the one-sided paired t-test, we accept the alternative hypothesis that the mean of the education group (3) is greater than that of the infrastructure group (1) at 0.05 significance level.

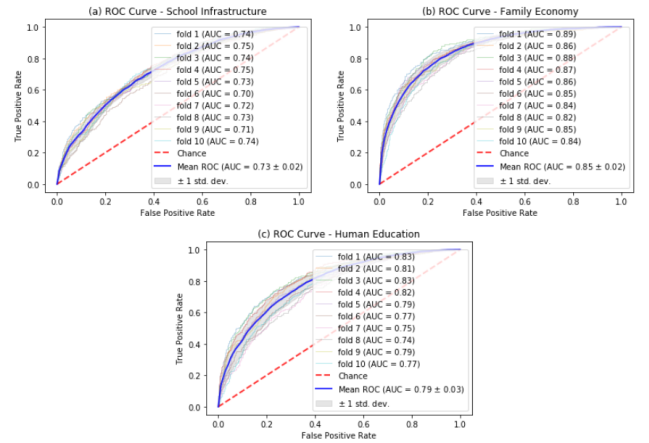

Figure 1: represents (a) the outputs for schools' infrastructure group, (b) the outputs for students' socioeconomic-cultural information group and (c) parents and teachers' level of education group.

The difference is highlighted even more when analyzing the number of variables in each group. Group 1 has 23 variables that represent the school structure while group 3 has only 3 variables, namely, the level of education of fathers, mothers and teachers. Analyzing group 3 in a logistic regression model on the whole dataset for assessing the features' influences according to their β coefficients, their predictive powers were in decreasing order, the father's education, the mother's education and the teachers' education. The qualification of teachers, in contrast to existing studies [18], does not have high explanatory power. This result is probably due to the fact that, in Brazil, the number teachers with M.Sc. and Ph.D. degrees in public secondary education is minimal (4.8% and 1.1%, respectively). Table 1 displays the beta coefficients of each variable and their p-value, well below the 0.05 significance level.

4. DISCUSSION

Several studies have improved the understanding of the determinants of school performance with the perspective of guiding educational policies. James Coleman, in 1960, had already identified the SEC factors of the students as the main determinant of their performance [13]. The correlation between parental education has been long established,

Table 1: Variable importance of the Logistic Regression model for group 3

Feature	β	p-value	Grain
Father's Education	3.87	0.00	Student Level
Mother's Education	2.94	0.00	Student Level
Teacher's Education	2.62	0.00	Teacher Level

as well [15, 11]. Other lines of research have also highlighted the relevance of aspects related to schools and teachers [18, 25, 14]. Much has been discussed in Brazil about the secondary education, as well as improving the budget allocation.

According to OECD, Brazil's public spending on education was close to the average of its member countries in the year of 2015 while the performance of Brazil in the last PISA exam was among the worst countries evaluated [27]. The quality of education still does not respond to the investments made. Therefore, it is crucial to improve the understanding of standardized national tests to help policymakers and education related institutions in developing educational public policies to produce an effective return on investment.

4.1 Parents Education as Proxy to SEC?

Separating out the independent effects of family education and SEC background is not a simple task. Some prior studies showed that those features are very correlated to family income, once parents who are more educated, earn higher salaries [24]. From another perspective, more education empowers parents and teachers to give the students better counseling and training. Some studies have tried to isolate the effect of each feature, aiming at determining causal relations between them in the educational outcomes [9].

This Subsection attempts to dissociate these characteristics to find out if the parents' education influences the student performance in the ENEM Exam for families with the same constant income. We started by considering only students from schools with infrastructure at basic level or above. To block any effect of economics, the students were undistinguishable by their family income which was kept constant. The performance was measured by the fraction (percentage) of good students in the sample, for each level of education.

Figure 2 shows the fraction of good students against the parents' education for each income value. It is clear that higher parents' education is associated with higher fraction of good students, with the income constant. Despite being a categorical feature, the level of education is associated with time of schooling, therefore suited to line graph representation.

Wrapping up, the students' performance on ENEM increases with their parents' level of education no matter their family income.

5. CONCLUSION

This paper has presented a comparative study of the influence of groups of predictors in the quality assessment of secondary school in Brazil to help policy makers in educational budget allocation.

Figure 2: Fraction of good students as function of their parents' education level. Ranges from "A" (no schooling) to "G"(postgraduate) for different family incomes indicated in the curves.

The experimental procedure had logistic regression as predictive technique and the comparison was performed with single-tailed t-test on a 10-fold cross-validation setting on paired test sets. The predictors (features) were partitioned into 3 groups as planned: Infrastructure, SEC information and Education. The performance metric was the Area Under the ROC curve (AUC_ROC) widely applied for assessing binary classifiers in domains such as medicine, telecommunications, artificial intelligence etc.

The results show that both the groups of features of parents' and teachers' education and of socio-economic-cultural information are more influential than the group composed of infrastructure features with statistical significance of 0.05.

Some research found in the literature argue that there is a high correlation among the predictors and that there could be causality in SEC information influencing the Education predictors. We have shown that Education predictors have a positive effect on the students' performance no matter the family income. Nevertheless, much more analyses have to be made in that sense.

Furthermore, ensemble of predictors in general achieve higher improvement in performance with the increase of complementarity among their modules [31]. That suggests that the higher increase of AUC in the combination of SEC and education features versus the combination of SEC and infrastructure features might be related to the smaller correlation of education compared to infrastructure both in relation to SEC features. This needs to be further investigated. It is also important to extend the analyses presented here for 2018 to several years to verify if the results found hold across time. We are carrying out the research and the preliminary results show that the same behavior holds for the previous 9 years as well.

It is important that experts in education and policy makers collaborate in this research to help improve the Domain-Driven Data mining approach by embedding their expertise in the solution development.

A Procrastination Index for Online Learning Based on Assignment Start Time

ABSTRACT

Despite decades of evidence on the impacts of procrastination on learner outcomes, the educational data mining community has procrastinated in applying measures of procrastination based on learner behavior. We advance a new measure of habitual procrastination within online learning, the *Procrastination Index*, which represents a learner's degree of procrastinating in when they start learning assignments (rather than when they complete assignments), relative to other learners within the same assignment (recognizing that different assignments may need different amounts of time). We apply this measure to data from over 100,000 students in 3,700 course sections from a large online learning platform. We find that students who habitually delay starting assignments have 21 times the risk of failing their courses than students who start on time. The result of this work is a straightforward and reliable Procrastination Index that generalizes across multiple academic disciplines, takes the individual features of assignments into account, is a strong predictor of academic performance, and provides an early signal to enable educators to design appropriate interventions for at-risk students.

Keywords

Procrastination, educational data mining, at-risk prediction

1. INTRODUCTION

Everyone procrastinates sometimes – even psychological researchers studying procrastination [8]. Despite procrastination's near-universality as a phenomenon, though, understanding is still incomplete as to what the full effects of procrastination are, where it emerges from, and how it can be combatted.

The relationship between procrastination and academic performance has been studied extensively. A meta-analysis by van Eerde [20] found that students who procrastinate generally receive worse course grades, a result seen in online learning environments as well [7, 12, 23]. On the other hand, other researchers have found evidence that students who procrastinate experience less stress and have better health than students who do not procrastinate [19].

A range of procrastination behaviors appear to be associated with poorer outcomes. Although procrastination has been defined rather

broadly as “the tendency to postpone an activity under one's control to the last possible minute, or even not to perform it at all” [6], most studies of procrastination involve homework or studying. However, even procrastinating on accessing course materials is associated with worse course outcomes [1]. Several factors appear to be associated with the decision to procrastinate, from anxiety and depression [3] (though see [19] for contrasting evidence), to self-handicapping [20], to poor self-regulation [12] or a lack of scaffolding for self-regulation [16].

However, there are key limitations to past research on procrastination. Importantly, most published papers on the topic assess procrastination through self-report measures [11,18]. While these self-report measures correlate to behavioral measures such as whether the student hands in assignments late and total time spent, the correlation is moderate, in the -0.2 to -0.3 range [20]. Furthermore, this is not quite the same as identifying actual procrastination – delaying in starting or working on an assignment. For instance, a student could start early, work hard throughout, but still turn in a difficult assignment late. It is also conceivable that some students may think they are procrastinating more than other students when they are not. Correspondingly, some highly successful students may procrastinate, starting at the last minute, and still turn in high-quality work on time. These students may not see themselves as procrastinators. Therefore, in this paper we attempt to hone more closely in on procrastination as a behavior, using learning system data to see when students start an assignment as well as when they turn it in, following recent work in the EDM community using log data to study procrastination [i.e. 4, 9, 13].

In the remainder of this paper, we begin by offering an operational definition of procrastination at the level of a learning task and then aggregating it to the level of a learner. We study the properties of procrastination according to this definition, and then investigate the empirical relationship between procrastination and academic performance. We embed this into an analysis of the probabilistic risk associated with different levels of procrastination according to our definition. Finally, we present linear and logistic regression models that use procrastination on tasks to predict students' final grade and whether they will pass or fail the course, as a method for applying this paper's findings into prediction-based interventions.

2. METHODS

We used two datasets for the study, Alpha and Beta, that were derived from the online learning system Connect, a web-based learning system actively used by approximately 6000 higher education institutions worldwide. Students use Connect to read a course text and complete assignments. Instructors can compose assignments from a question bank as well as creating their own assignments. Both instructor-created and question bank assignments can be auto-graded. Connect records assignment start and end time, and the grade. Dataset Alpha is a heterogeneous

Lalitha Agnihotri, Ryan Baker and Steve Stalzer "A Procrastination Index for Online Learning Based on Assignment Start Time" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 550 - 554

dataset spanning multiple institutions. Alpha consists of 2,666,617 assignment submissions by 102,506 students on the platform during the Fall 2018 semester. The assignments span 3,681 courses, 42 disciplines, and 3,681 instructors at 1,216 institutions. Although the platform is used internationally, we restricted the analysis to US institutions to limit regional issues, policy differences in data use, and possible cultural differences in procrastination. The students submitted about 112,025 unique assignments in various courses. The courses are set up by instructors and differ in terms of course length, the number of homework assignments (the sample was restricted to courses with at least 10 assignments), and what percentage of the overall course grade is made up of the assignments on the Connect platform.

Dataset Beta, a more homogeneous data set from a single institution, also contained the final course grade for each student. The dataset, collected in the 2018/2019 academic year, consists of 98,201 assignment submissions on 5,986 assignments by 1,022 unique students in 298 sections of 37 courses in 28 disciplines. Many students were included in more than one course for a total of 3758 student-sections. The courses are designed with a regular spacing of assignments, four per week in each of eight weeks, for a total of approximately 32 assignments per course. In these courses, assignments on Connect are worth 80% of the course grade.

3. OPERATIONAL DEFINITIONS

3.1 Task Procrastination

All procrastination is delay, but not all delay is procrastination [15]. The central concept in procrastination is task delay – i.e. delaying in starting or completing a task that needs to be completed to accomplish some goal. When the student considers when to start an assignment, the student must decide, explicitly or implicitly, how much time they will need and, therefore, when they should start. An error in estimating this correctly places the student at risk of a poor grade. As a first step, let us postulate that for each assignment there is a threshold time to start the assignment, τ_t , a point after which we cannot reasonably expect most students to perform well on the assignment due at time τ_d . Note that this is a simplifying assumption: student knowledge of the topic and general ability likely varies, causing the true threshold start time to vary between students for a given assignment [cf. 10].

Consider two scenarios. In the first, a student begins a task at time τ_s before the threshold time τ_t and is therefore likely to complete the task and complete it well.

Figure 1 "Safe Zone" for starting an assignment

In the second scenario, a student begins a task after the threshold time, and is not likely to obtain a good grade on the assignment.

Figure 2 Case when start time is after threshold time

But how does one find τ_t ? Or in other words, how do we assess task procrastination for a specific task given that the time needed to complete will vary from task to task? We can answer this question by considering the average z-scores derived based on each assignment rather than the absolute scores. Figure 3 shows the average grade z-scores students achieved based on when they start an assignment. By the 60th percentile, the score is below the mean performance on the homeworks. Near the 75th percentile, the score has dropped to 10% less than the mean and the decrease accelerates.

Based on these findings, we can heuristically set the threshold time τ_t for an assignment to be κ^{75}_s , the start time at which 75% of students have started the assignment. Setting κ^{75}_s as the threshold time, we can assign each student and each assignment a Boolean value to indicate whether the student started their assignment early enough or whether they procrastinated. A value of 0 means the student started their assignment early enough that we can say they did not procrastinate. A value of 1 means the student procrastinated. In other words, if τ_s is before κ^{75}_s , the student started on time. If τ_s is after κ^{75}_s , the student procrastinated. In the unfortunate special case where more than a quarter of students start after the due date, seen in approximately a quarter of assignments, we set τ_t to 0 -- starting after the due date is by definition procrastination, since no one can complete an assignment in less than 0 seconds.

$$\kappa^{75}_s = \kappa^{75}_s \text{ if } \kappa^{75}_s \leq \tau_d$$

$$\tau_d, \text{ if } \kappa^{75}_s > \tau_d$$

Task procrastination is then defined as follows. It is set to 0 if the start time is before the fourth quartile threshold κ^{75}_s as defined above. It is set to 1 if the start time is after this point or if no start time exists (the student never started the assignment)

$$P = 0 \text{ if } \tau_t < \kappa^{75}_s$$

$$P = 1 \text{ if } \tau_t > \kappa^{75}_s, \text{ or } \tau_t \text{ is null}$$

3.2 Learner Procrastination

We can now use this assessment of Task Procrastination t as the basis for creating a Learner Procrastination Index (PI). For example, the following array represents a student S1 and their procrastination pattern (again, 1 represents procrastination and 0 represents not procrastinating). Take a hypothetical student, Chris. Chris started the first two assignments on time, and procrastinated on the remaining ones, until beginning the final assignment on time.

$$P_{\text{Chris}} = [0; 0; 1; 1; 1; 1; 1; 1; 1; 0]$$

From this, we compute Chris's Procrastination Index (PI) as the percentage of 1s on a scale from 0 to 1, 0.7 based on the above.

$$PI = \text{mean}(P_{\text{Chris}})$$

Figure 3 Starting Percentile vs. Z-Scored Grade

Figure 4 Histogram of PI for the 100k+ students

A PI of 0 means that student began every assignment on time. A PI of 1 means that the student procrastinated on every assignment. Figure 4 represents the distribution of the Procrastination Index for the over 100K students in Dataset Alpha.

4. Analysis of Procrastination, Performance, and Outcomes

With this operational definition of procrastination, we can now examine the relationship between procrastination and performance, shown in Figures 5 and 6. Figure 5 shows the average of the score on assignments in Connect for the dataset Alpha and figure 6 shows the average of the final grade on the course for dataset Beta. The average course grade declines as the Procrastination Index increases. The Pearson correlation between Procrastination Index and grade was found to be -0.67 and -0.69 for the datasets Alpha and Beta respectively, $p < 0.001$ for both datasets. It is worth noting that these correlations are double to triple the magnitude of the correlations to grades previously reported for self-report measures of procrastination ($r = -0.2$ to -0.29 ; [i.e. 20]). Furthermore, as Figure 6 shows, the relationship is fairly consistent. Students who procrastinate under 5% average an A grade; students who procrastinate under 20% of the time have above a B average. Students who procrastinate under half the time receive more Bs and As than Cs. As the graph shows, there is a relatively steep drop-off in grade around a PI of 50%. Students who procrastinate 95% of the time tend to obtain a D or F.

In the remainder of this section, we will analyze the difference in course grades between students who frequently procrastinate (high Procrastination Index; “high PI”) and students who procrastinate less often (“low PI”). These cut-offs are somewhat arbitrary, and we set them using course grades; although this creates some circularity, the resultant analysis is correlational rather than causal and therefore should be considered descriptive in nature.

Given the sharp drop-off in grades seen at a Procrastination Index of around 50% (see Figure 6), we can consider students who procrastinate more than half of the time to have high procrastination. There is not quite as clear a cut-off for low procrastination, but given that 20% marks a point where students tend to get Bs or better, we can consider 20% a cutoff for low procrastination. To create a group of students with medium PI for analysis, we chose PI between 0.3 and 0.4 to have values evenly between low PI and high PI while having a gap between groups.

Figure 7 shows the probability distribution function of Dataset Alpha for performance for different PI groups. Students with a high PI (red) are distributed at the lower end of the performance range. Students with low PI (green) tend to have higher performance and have low probability of obtaining an average score of under 60%.

Figure 5 PI vs. Mean Assignment Score

Figure 6 PI vs Mean Course Grade (A: 4, B: 3, C: 2, D: 1, F/W:0)

4.1 Procrastination and the Risk of Failure

Based on these categorizations, we can study the degree to which students with high and low PI are at different levels of risk of failing a course. For Dataset Alpha, we classify a student as passing if they obtain a grade of 70 or higher for the course. For Dataset Beta, we have obtained the actual final grades from the university. A/B/C is defined as pass; D and all other grades (F and a never-completed “incomplete” or withdraw) are treated as a failing grade.

Figure 7 Performance (mean assignment score) Distribution for Different PI ranges for Dataset Alpha

Within Dataset Alpha, high PI students fail 71.5% of the time, while low PI students fail 3.4% of the time ($RR = 21$). Specifically, we compute the risk ratio (RR) for the likelihood that a student with a high PI will fail the course, compared to the likelihood that low

PI student will fail. We also compare the score distributions with Cliff's Delta, a measure of the degree of overlap between two distributions. Cliff's Delta scales from -1 to +1, where +1 and -1 indicate no overlap (in the two directions), 0 indicates total overlap, and values in between indicate partial overlap.

Dataset Beta, high PI students fail 54.6% of the time, while low PI students fail 1.1% of the time (RR=50). The Cliff's Delta is 0.82 for dataset Alpha is 0.82 (median score 91 vs. 54) and 0.77 for Beta (median score 92 vs. 67), indicating very little overlap between the two distributions. Nearly every student in the low PI group outscores every student in the high PI group.

4.2 Procrastination as a Predictor of Outcomes

In this section, we investigate PI as a potential predictor of final score and course outcome, using linear regression to predict the final score and logistic regression model to predict if a student would pass or fail the course, with a training-test split. We find that PI can be used to predict the final score, with $R^2 = 0.45$ for both datasets, and RMSE of 15 (Alpha)/ 17 (Beta) grade points. Logistic regression obtains a successful AUC ROC of 0.86 for both datasets. Even if we vary the cut-off for task procrastination, considering the 50th, 60th, 75th, 85th, and 95th percentile, and re-fit the model, model performance remains high. As Table 1 shows, the models maintain reasonably high AUC ROC across thresholds, with moderately higher AUC ROC with procrastination cut-offs from the 75th to 95th percentile of time. However, it is probably not useful for intervention to select a threshold where 95% of students have already started the assignment. Note that the recall values in this table do not fit the intuition that recall should go up for lower thresholds; this is because the threshold is at the level of individual assignments, whereas the logistic regression model sets a second cut-off at the level of students across assignments.

Table 1 Performance of logistic regression models that use different start time thresholds for procrastination.

Threshold Percentile	Average Precision	Average Recall	AUC ROC	Precision of Students who fail	Recall of Students who fail
50	69	59	0.8	55	22
60	72	63	0.83	60	31
75	76	67	0.86	65	40
85	78	69	0.87	68	44
95	78	69	0.87	68	43

5. DISCUSSION AND CONCLUSIONS

Though there has been considerable work on procrastination over the last decades, much of this work has looked at self-report measures or submission time. In this paper, we consider when students start assignments, relative to other students' work on the same assignment, which can function across contexts and can be aggregated across a course. Our aggregation, termed the Procrastination Index, is correlated with not only score within the Connect platform, but with the overall grade on the course, and can predict student grades, achieving double to triple the correlation to student outcomes seen for prior self-report measures [i.e. 20].

We can use early detection of procrastination to message students and to help them develop good habits. Even students who are performing well, but frequently procrastinate, may benefit from developing better habits – procrastination may become a bigger problem for these students when they reach more difficult material. Finishing tasks just in time can make sense in specific cases – but if students develop a general strategy of procrastinating, it may misserve them later [2]. Several interventions may be successful at

helping students to work effectively. [21] have recently published a meta-analysis of different interventions designed to reduce procrastination, looking at which type of intervention leads to the strongest reduction. They investigated interventions involving self-regulated learning strategies (including time management), cognitive-behavioral therapy, and assertiveness training. They found that cognitive-behavioral therapy led to significantly less procrastination, and that assertiveness training actually led to significantly more procrastination. However, all of the interventions investigated in [21] were intensive. By contrast, [2] has proposed a way for students to offer their own deadlines to avoid a last minute rush to complete, leading to improved grades. In an automatic system, we can envision a system enabling students to suggest deadlines or presenting additional deadlines (for, say, a milestone that represents completing half the homework) to help them break down the task and reduce procrastination. It may also be possible to create automated interventions inspired by cognitive-behavioral therapy, although it is unclear whether they will work as well as the full therapeutic approach.

It remains to be seen what interventions are most effective at reducing procrastination and improving outcomes in a scalable fashion. As with other domains such as help-seeking [cf. 17], the relationship between procrastination and outcomes is probably not fully causal and it may be possible to reduce procrastination without improving outcomes. Finding the right intervention(s) to improve outcomes will be beneficial not only in improving outcomes but also in understanding whether – and how – procrastination has causal impacts on learning. More generally, a fuller understanding of procrastination may help us to better alleviate its impacts. Do students procrastinate as a habit or is it an ongoing error in their estimation of their time demands? What role do boredom and lack of engagement play? Better understanding the answers to these questions may ultimately lead to redesign of courses and/or assignments to better keep students engaged in their learning in a steady fashion throughout the semester.

In this paper, we have proposed a way to identify procrastination in students based on their interactions with an online learning system, that accounts for start time relative to other students. The PI indicator seems to generalize well across many different class sections, subject areas, and disciplines. We have been able to apply it to over a hundred thousand student scores in the Connect learning platform as well as with around 3,700 students at a specific institution with their final course grades. The correlation of Procrastination Index to the outcome in the course is around -0.7. The PI on a course can be used in a linear regression model to predict the final score, achieving an R^2 of 0.45, substantially higher than the predictive power of self-report measures of procrastination. For predicting pass or fail using a logistic regression model based solely on procrastination, we are able to achieve an area under the ROC curve of 0.86. We plan to use this research to improve our products – targeting content that is often procrastinated on for improvements -- and develop ways to nudge students to work more effectively and finish their tasks earlier. If we, as a field, stop procrastinating on this important issue, the impact on our students may be profound.

ACKNOWLEDGMENTS

We would like to thank the developers of the Connect platform for supporting our data collection efforts, and Alfred Essa, for initial leadership of this research while at McGraw Hill.

ABSTRACT

Recent years have seen a growing interest in learning analytics for computer science education. The significant growth of computer science enrollments coupled with the labor-intensive nature of human assessment has fueled the demand for automated assessment of student programs. Effective automated assessment tools can bridge the gap between the demand for support and restricted instructional resources by providing adaptive formative and summative feedback. Following an evidence-centered assessment design approach, we have devised an automated assessment framework for middle grades computational thinking. We report on an evaluation comparing regression models including ridge, lasso, support vector, and Gaussian process regression models utilizing a structural n -gram feature set to infer scores for students' programs. The results show that Gaussian process regression outperforms other regression models with respect to mean squared error and adjusted coefficient of determination. They also show that the framework provides a promising approach with regard to dealing robustly with noise to effectively model student computer science competencies.

1. INTRODUCTION

Computer science (CS) has become a foundational skill for students to thrive in a digital economy [14, 28]. To prepare students for future studies and science and technology professions, it is essential to ensure that they acquire robust CS competencies. A key strategy for developing CS competencies is through programming. However, learning how to program is challenging for novices [12, 13]. Hence, novice programmers need significant scaffolding to support understanding and effective use of CS concepts. Effective assessment of students' understanding of essential CS concepts is an important step in providing students with appropriate scaffolding and feedback [11, 17]. Because the growth in demand for CS education has outstripped the supply of qualified teachers, providing every student with individualized, high-quality, and

timely support and feedback is challenging. Effective automated assessment can guide adaptive formative and summative feedback to support effective CS education.

In order to provide students and their instructors with reliable automated assessments, we follow a hypothesis-driven learning analytic approach [4] based on Evidence-Centered Assessment Design (ECD) [20] to assess students' competencies in CS concepts as demonstrated in their programs. Following this approach, we first identify CS concepts that students need to master in order to solve a particular computational thinking-focused problem with a block-based programming interface embedded in the ENGAGE game-based learning environment (Figure 1). We then collect log data from students' interactions with the game. Content area experts then analyze the structured log data as evidence of knowledge (or lack thereof) of target CS concepts. Deriving evidence from students' proposed solutions, we assess their mastery of identified CS concepts, such as creating appropriate algorithms and programs, and appropriate usage of computer science constructs, such as loops and conditionals. We encode programs as structural n -grams to extract essential structural and semantic information within them. Finally, we utilize regression models including ridge, lasso, support vector regression (SVR), and Gaussian process regression (GPR) models on the generated feature set to infer students' competencies for knowledge of CS concepts and practices. We utilize GPR models to handle the remaining noise in the dataset. Evaluation results suggest that the models accurately model students' CS competencies and are robust to noise.

2. RELATED WORK

Two primary approaches have been explored for assessing text-based programs: dynamic and static assessment [5, 15]. In dynamic assessment, programs are executed against pre-defined test data to determine their correctness. Evaluation metrics include successful compilation, consideration of security threats, correct outcome, and efficiency metrics such as CPU runtime and clock time [15, 16, 25]. In contrast, static assessments are capable of assessing programs that are not necessarily complete. To perform a static assessment, an intermediate representation of the program needs to be generated from the source code. Examples of intermediate representations are textual representations, abstract syntax trees, control flow graphs, and program dependence graphs. After forming the intermediate representation, the representation is analyzed for its correctness, efficiency, and quality [26]. Although block-based programming differs from text-based programming in syntax and visual representation, they can both be transformed into the same intermediate representation. Therefore, the techniques used for

assessing one type of programming from this representation can be readily adapted to assess the other type of programming [9, 10].

Limited previous work has focused on assessing students' understanding of underlying CS concepts from their programs. In this paper, we propose an automated assessment framework designed following a hypothesis-driven learning analytics approach to assess students' programs based on their mastery of underlying CS concepts for the particular problem at hand. We use the underlying CS concepts to label students' programs with their grades. We then transform students' programs to a feature set containing salient features that can serve as evidence for students' proficiency of this underlying CS concepts. Utilizing the labeled data and the extracted feature set predictive models can identify students' mastery of CS concepts.

3. ENGAGE LEARNING ENVIRONMENT

To collect data on middle grade students' programming trajectories, we conducted a study with a game-based learning environment, ENGAGE, that is designed to teach CS to middle school students [2, 18]. The game features a rich, immersive 3D storyworld (Figure 1), in which students play the role of a specialist who is sent to investigate an underwater research facility that has lost communication with the outside world through suspicious activities of a rogue scientist. In the learning environment, students navigate through a series of interconnected rooms by solving a set of computational challenges. Each of the challenges can be solved either by programming devices within the room or interacting with devices in reference to their pre-written programs. Students program the devices with a visual block-based programming language interface (Figure 1, Right) [1, 19].

In this work, we focus on students' problem-solving approaches within a specific level of the game where students write a bubble sort algorithm to order a set of containers (Figure 1). This room has two devices: a containment device that holds six randomly positioned containers and a lock device that opens only when the containers are sorted in the increasing order. The player can exit the room through a door by correctly implementing bubble sort and executing the lock program when the containers are sorted. The lock has a pre-written program that will check the positions of containers and opens if they are in the correct position. The containment device provides students with the necessary blocks for implementing a bubble sort algorithm using a small robotic cart inside the device's protective housing. Students can choose from 6

types of readily available blocks to write their program. A sample correct solution for this challenge is shown in Figure 1 (right). Students need to test the correctness of their program in two steps. First, they need to run the bubble sort device to sort the containers. Second, they need to run the open lock program which checks if the containers are sorted and opens the door accordingly.

4. METHODOLOGY

We utilize supervised learning to assess students' programs. The supervised learning approach consists of three primary steps. First, we label the training dataset in accordance with a rubric designed based on essential CS constructs. Second, we extract features from students' submitted program snapshots that represent their understanding of CS constructs. This is accomplished with a novel approach that encodes students' programs in terms of structural n -grams. Third, we create models induced from the structural n -gram-based feature set to infer students' scores. In this study, we utilize a variety of regression models including linear, ridge, lasso, SVR, and GPR models to predict students' programs' scores.

4.1 Data Annotation

We use evidence-centered assessment design (ECD) to create a rubric for labeling students' programs [22]. Following an ECD approach, we identify explicit learning outcomes and measures to inform our rubric [7]. The relevant CS concepts are identified and used to develop the specifications of a rubric to assess students' proficiency of identified CS concepts. Student actions during the learning task are used as evidence for predicting mastery of the identified CS concepts [24]. Following this approach, we design a rubric that utilizes evidence rules specific to the bubble sort challenge in the ENGAGE game-based learning environment. We use this rubric to manually label students' programs [3, 4].

As students interacted with the learning environment, all of their interactions with the game were logged. For this study, we collected data from five classrooms across three schools in the United States. We collected data from 69 students' interactions with the bubble sort challenge in the game-based learning environment, for a total of 1,570 programs that we used as the training dataset. In this rubric, the range of possible scores is between 0 to 22. To validate the labeling process, two human annotators with a computer science background separately labeled 20% of the entire submissions, achieving an inter-rater agreement of 0.856 using Cohen's kappa [8]. Before tagging the remainder of the corpus, all instances that were tagged differently were discussed. Afterwards,

Figure 2: AST generated from a sample program submitted for the bubble sort challenge and its hierarchical and ordinal n -gram encoding. (Left) An AST and its partial *hierarchical* unigrams, bigrams, and 3-grams marked by green, blue and purple ovals respectively on the left and the partial feature set generated from hierarchical n -gram encoding of the AST along with feature-level frequencies on the right. (Right) An AST and its *ordinal* unigrams, bigrams, and 3-grams marked by green, blue and purple ovals respectively on the left and the partial feature set generated from partial ordinal n -gram encoding of the AST along with feature-level frequencies on the right.

one annotator tagged the remainder of the dataset. The annotated dataset is used as the corpus for our prediction task where the assigned scores serve as the ground-truth for our data corpus.

4.2 Feature Engineering

In order to infer students' scores based on their submitted programs, we extract structural features that are representative of the semantic information in students' code. To extract features that capture essential structural and semantic information stored within the programs, we perform a structural n -gram encoding of the programs' abstract syntax trees (ASTs). Since the programs are stored as programming snapshots, we first apply an intermediate transformation from programming snapshots to their corresponding ASTs [23]. We then encode the generated ASTs into their corresponding structural n -grams. After generating the ASTs from their corresponding programs, we use a structural n -gram encoding to capture essential structural information characterized within the programs. Two important structural information types in ASTs are *hierarchical* and *ordinal*. The hierarchical information encodes what blocks are nested under another (i.e., a vertical relationship in AST), and the ordinal information encodes the placement order of blocks (i.e., horizontal relationship in AST) that are nested under the same parent node. We extract n -grams with varying lengths of n to capture the most fine-grained structural information present in an AST. We repeat the n -gram encoding process separately for hierarchical feature extraction and ordinal feature extraction. We then merge the two feature sets together to build the final feature set containing both hierarchical and ordinal n -gram encodings corresponding to each program keeping only one copy of the generated unigrams. The occurrence of similar n -grams for n values more than one (unigrams) in both hierarchical and vertical encodings demonstrate presence of different structures in the AST and thus, both will be preserved.

Figure 2 shows an AST generated from a sample program along with its partial hierarchical (left) and ordinal (right) n -gram encoding. In Figure 2 (left), each colored circle shows the hierarchical (top to bottom) n -gram encoding of a specific n . In this example, we have hierarchical encoding of n -grams of size one (green ovals), two (blue ovals) and three (the purple ovals). The frequency values for each n -gram encoded feature are shown beside the AST. All of the other n -gram feature values are zero since they are not in this AST. Figure 2 (right) shows the same sample AST with its ordinal (left to right) n -gram encoding. In this example, we

have an ordinal encoding of n -grams of size one (pink ovals), two (purple ovals) and three (the green ovals). Similar to Figure 2 (left), the frequency values for each n -gram feature is shown besides its corresponding AST in Figure 2 (right).

4.3 Inferring Program Scores

We trained a variety of regression models on the structural n -gram-encoded features to infer the scores of students' programs. In particular, we used linear regression as the baseline regression model, and four additional regression models: ridge, lasso, support SVR, GPR models. Ridge and lasso regressions are characterized by their utilization of L1 and L2 regularization, respectively, which address overfitting and variance issues in comparison to linear regression. We use SVR and GPR models since their utilization of kernels makes them a suitable candidate for datasets similar to ours where the number of features is relatively high compared to the number of data points. Finally, we utilize GPR to handle the noise resulting from the subjective nature of human grading [6, 27]. To infer students' program grades using the n -gram encoded feature set (we set the maximum n to 4 for hierarchical n -grams and 3 for ordinal n -grams in this work), we use a 5-fold cross-validation approach to tune the hyperparameters of ridge, lasso, and SVR regressions, and to identify the appropriate kernel for the GPR. After the hyperparameter optimization process is complete, we use 10-fold cross-validation to train and evaluate each regression model.

4.3.1 Linear Regression

Linear regression is a simple regression approach that works under the assumption that there is a linear relationship between features and the predicted value. The results of applying a 10-fold cross-validation evaluation on the n -gram encoded feature set resulted in a Mean Squared Error (MSE) of $3.03\text{E}+24$ and an R-squared of $1.19\text{E}-23$. The high MSE value reported by the linear model trained with our feature set is understandable since the high number of features in our dataset dramatically increases the complexity of the model, which in turn causes overfitting of linear regression-based predictive models to the training data.

4.3.2 Ridge Regression

To reduce the variance error, ridge regression includes a penalty term in the optimization. We used the set $[0.05, 0.1, 0.5, 1.0, 10]$ to tune the value for λ , the penalty coefficient, and found $\lambda=10$ to be

the best value for our regression task. Applying ridge regression on our dataset resulted in an MSE of 5.24 and an R-squared of 0.81. We can see that ridge regression considerably outperformed standard linear regression with respect to both MSE and R-squared.

4.3.3 Lasso Regression

Unlike ridge regression, lasso regression includes a penalty term that allows the optimization process to shrink weights to zero if necessary. As a result, lasso regression can reduce overfitting as well as perform feature selection. We used the set [0.05, 0.1, 0.5, 1.0, 10] as in ridge regression to tune the value for λ and found $\lambda=0.05$ to be the best value for λ . Utilizing lasso regression resulted in an MSE of 6.30 and an R-squared of 0.77, which also outperformed standard linear regression models with respect to both MSE and R-squared.

4.3.4 Support Vector Regression

Support vector regression (SVR) use kernels to transform data from a non-linearly separable space to a linearly separable space. For our regression task, we explored with linear, polynomial, and radial basis function (RBF) kernels. For each kernel, we tuned the hyperparameters of penalty parameter (C), epsilon, and kernel coefficient (gamma). For polynomial kernels, we also tuned the parameter of the kernel projection ($coef0$) and degree hyperparameters. Utilizing 5-fold cross-validation, we found the polynomial kernel with a degree of four to be the best kernel for our dataset. Also, the grid search identified $C=100$, $coef0=1$, degree= 4, epsilon=1, and gamma= 0.001 as the best parameters for this kernel. Incorporating the SVR model resulted in an MSE of 5.09 and an R-squared of 0.82. SVR performed better than both ridge and lasso regressions in terms of MSE and R-squared. This could be due to the fact that kernel methods perform effectively on datasets with a feature set that is relatively large compared to the size of the dataset.

4.3.5 Gaussian Process Regression

GPRs provide an analytically tractable solution for regression problems with an infinite or uncountable set of considered basis functions [21]. We hypothesize that the GPR will outperform other regression techniques due to its capability of handling noise and its propriety for our dataset. To search the optimal kernel for GPR models, we cross-validated the model for radial basis functions (RBF), rational quadratic, and Matern kernels, and we found RBF to perform the best on our dataset. To find the optimal set of hyperparameters and prior parameters of the GPR, we follow the process of maximizing the probability of observing data given hyperparameters of the process (i.e., marginal likelihood). In this work, we use a limited-memory BFGS optimization technique to maximize the log marginal likelihood conditioned on the length vectors and the noise level of the kernels.

Applying GPR resulted in an MSE of 1.71, and an R-squared of 0.94. GPR performed significantly better than other regression models. Not only is GPR a kernel-based model similar to SVR, but by adding an additional noise kernel it can also account for the potential noise in our dataset. As a result, it is expected that the GPR model outperformed other models in our prediction task. Results of applying each of the regression models on the structural n -gram encoded feature set is shown in Table 1.

Table 1. Average predictive performance of regression models trained with the structural n -gram feature set

Regression	MSE	R ²
Linear	3.03E+24	1.19E-23
Ridge	5.24	0.81
Lasso	6.30	0.77
SVR	5.09	0.82
GPR	1.71	0.94

5. CONCLUSION

Rapidly growing interest in computer science education and students' need for guided practice of CS concepts have created a significant need for accurate and effective automated assessment. In this work, we proposed a novel structural n -gram encoding scheme to extract important structural and semantic information from students' programs. The n -gram encoding approach, coupled with data labeled using the ECD-based rubric enables our assessment framework to model evidence from programs that are representative of students' mastery of identified CS. We apply a variety of regression models on the n -gram encoded feature set to infer students' program scores. The results of our prediction demonstrate the effectiveness of the n -gram encoded feature set in capturing important semantic and structural information in students' programs. All regression models performed better than the baseline model, linear regression. Furthermore, GPR outperformed other models in terms of both mean squared and R-Squared errors. This confirms expectations since GPR models can handle noisy data and are particularly efficient for datasets in which the number of features is particularly high relative to the number of data points. Our automated CS competency assessment framework can be generalized to assess any well-structured programs in learning environments that present students with well-structured programming assignments. Furthermore, the ECD approach can facilitate rubric design and assessment for non-expert CS teachers while providing them with automated assessment of students' programs.

Several directions for future work are promising. First, it will be important to expand the assessment framework to accommodate more open-ended programming assignments. Second, information from successive submission of students can be extracted to analyze students' patterns of developing CS competencies.

ABSTRACT

Physics has always been a challenging subject for many students. Research also shows a gap between instructional goals and actual student learning in introductory physics courses. This study focuses on two online first-year courses that cover classical mechanics of the physics curriculum at an open university in Canada. Each of the two courses is developed around a textbook and includes a locally created study guide enriched with animated videos, dynamic diagrams, and interactive exercises. This study aims at introducing a simple feature to provide physics students with personalization based on their background knowledge and at examining students' interactions with the online course materials. Relevant educational data are compiled using checkpoint quizzes, self-reflection questionnaires, examinations, and log data collected through the learning management system (Moodle). In addition, peer faculty feedback is collected. Positive correlations are expected between regular learning behavior and engagement in personalized support and students' performance on examinations.

Keywords

Data mining, Learning analytics, Learning management system, Moodle, Introductory physics, Distance education, Online learning, Personalized support, Learning behaviours.

1. INTRODUCTION

Despite its significance as a foundation for modern technological achievements, physics is perceived as a challenging subject by many students. In 1987, a prominent physicist, Richard Feynman (1918 – 1988), suggested “that physics shouldn’t be taught in high school because most of the teachers lacked a passion for the subject” [1]. Researchers at the time also pointed out an alarming gap between expected learning outcomes and actual student learning in introductory physics courses [2]. This old problem called for a reconsideration of the traditional approach to teach this important subject.

The argument surrounding physics education is especially relevant to the distance education (DE) model, which is witnessing a period of accelerated evolution, powered by advancements in digital technology. Despite challenges linked to the nature of DE, the flexible presentation format of online courses breaks some of the traditional barriers and allows for new possibilities. This leads to the question about effective instructional design features in introductory physics courses that cater to all students and provide successful online experiences [3-5].

Farook Al-Shamali, Hongxin Yan, Sabine Graf and Fuhua Lin "Educational Data Mining and Personalized Support in Online Introductory Physics Courses" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 561 - 564

An online course delivered through a learning management system (LMS) can provide a multitude of data and information related to students' interactions with the course materials. Knowledge obtained from mining and analyzing available data, in combination with plug-in adaptive learning systems, can be used to guide individual students to study more effectively and to improve the quality and presentation of the course materials [6-8]. For instance, recent studies suggest that one of the common (and apparently less productive) students' practices in studying physics involves the “cramming” of relatively large quantities of the subject matter during short periods preceding exams [5,9]. Also, Imhof et al. indicated a “negative relationship between prior knowledge test score and predicted learning progress” in physics modules [3]. Even though the investigated courses cater to adult learners, not all students can effectively acquire online learning abilities [10]. Such observations highlight how personalized and adaptive learning are potentially effective concepts in the design of online physics courses.

A major advantage of the traditional face-to-face (F2F) educational model is the direct student-teacher interaction, which permits the instructor to make timely adjustments to the subject matter and teaching style to ensure better students' engagement. The assumption here is that the instructor is sufficiently flexible to make the required accommodations, and the size of the classroom is reasonably small so that accommodating individual students becomes practical. In an online class, however, students interact less with a dedicated teacher but more with the LMS and the course materials. This is especially true in the asynchronous delivery model, where course content (typically) consists of rigid learning resources developed with the “one-size-fits-all” teaching concept. Such a delivery format does not take into consideration the “individual differences, personal needs and personal development” of all students [7].

Chaw and Tang found that students' use of the LMS is correlated with the service quality it provides [11]. Also, the quality of an online course should be enhanced when instructors are equipped with effective learning analytics and data mining tools [12,13]. In particular, proper utilization of educational data promises to facilitate effective personalized learning in online courses, including personalized feedback and recommendations for extra learning materials [8,14-18]. Such individualized support is particularly important in physics courses where conceptual understanding is typically constructed vertically using scaffoldings provided by essential mathematical tools. Therefore, physics students are expected to appreciate personalized learning environments that evaluate their progress, fill individual knowledge gaps, and sharpen specific math skills if needed [19,12].

Learning analytics (LA) and educational data mining (EDM) have been used for a range of applications, including personalized learning [20]. In this paper, we introduce a work-in-progress

research project that uses LA and EDM to examine students' interactions with the course materials in two online physics courses. More specifically, the project introduces a simple and practical adaptive feedback module that can be easily integrated into the LMS. It provides a level of personalization based on students' background knowledge directed toward reducing the knowledge gap among a diverse student group.

2. PHYSICS COURSES

This study focuses on two first-year physics courses offered online (through Moodle) at Athabasca University in Canada. The first course is an algebra-based introductory physics and covers conventional topics in classical mechanics. It is considered among the top 50 high enrollment courses at the university, with effective annual registrations that exceed 400 students. The second course is physics for scientists and engineers, which is the calculus-based version of the first course. Both courses share a mandatory home lab component [21].

The textbook is an essential educational resource in a typical physics course. However, traditionally, the textbook is written with the conventional classroom in mind. Therefore, in DE, the study guide becomes an important component that guides the student through different learning activities and course assessments. In particular, the study guides for the two courses are designed to complement the textbook and provide additional reading (and audiovisual) materials related to each unit and lab experiment (see Figure 1). An important component of the study guide consists of detailed solutions to physics problems related to each unit in the course.

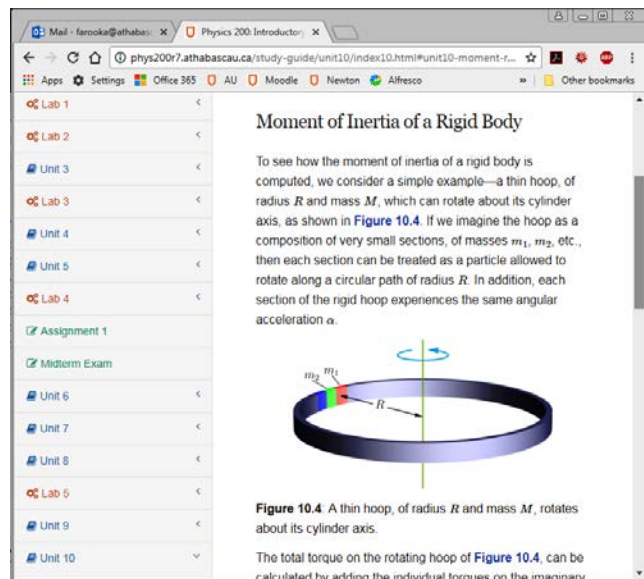

Figure 1. Snapshot from the introductory physics study guide.

Recent revisions of both investigated courses involved the production of an online study guide written in HTML with MathJax scripting of the LaTeX code. The improved version of the study guide is enriched with dynamic and interactive diagrams created using Mathematica (<https://www.wolfram.com/mathematica/>). This is in addition to the free simulations of the PhET Project (<https://phet.colorado.edu/>). Students are expected to benefit from the interactivity and the real-time visualization of interactions between position, velocity and acceleration, especially in two and three dimensions. This includes the kinematics and dynamics of

projectiles, circular motions, collisions, etc. Some of the interactive diagrams are complex enough to be considered virtual labs that simulate real-life situations.

The course development team constructed a website for the study guide that is accessible through the course homepage on Moodle and supporting responsive (mobile optimized) features. This is in addition to the textbook, which is accessible as an eTextbook through a separate link. One of the courses uses an open educational resource (OER textbook). The new design approach to the study guides received positive feedback from peer faculty members. However, even though some design considerations are integrated into the course for collecting feedback, our knowledge of students' interaction with the course content is limited.

3. RESEARCH Questions

In this study, we investigate the effectiveness of automated personalized support provided to students at specific milestones in two online physics courses. More specifically, the study addresses the following research questions:

- Is there a correlation between the academic performance of individual students and their response and behavior concerning the adaptive feedback module?
- How do learning behaviour and study patterns influence students' overall academic performance?
- What course elements are most effective regarding the adaptive feedback module?

4. RESEARCH PLAN

Relevant educational data are compiled using checkpoint quizzes, students' self-reflection questionnaire, course assessment results, and log data collected through the LMS (Moodle). In addition, peer faculty feedback will be collected.

4.1 Personalization through checkpoint quizzes

For the proposed personalization feature, the online study guide for each course is divided into five sections covering the main topics in each syllabus: kinematics, dynamics, energy & momentum, gravity & rotational motion, and elasticity & equilibrium.

Before starting a new section, a student is encouraged to complete a multiple-choice checkpoint quiz that is automatically marked by the LMS. The optional quiz is used as a checkpoint to assess the student's mastery of the topics in each section (see Figure 2). Based on the responses, the system may suggest the student proceeds to the next unit in the course or recommend a set of additional learning resources that may help strengthen the student's specific background concepts required by the upcoming topics. For example, a student who underachieved on the quiz questions related to rotational motion could be directed to a relevant video (such as <https://youtu.be/garegCgMxxg>) from the Khan Academy (<https://www.khanacademy.org/>), the problem-solving examples created in the study guide, or a section of the textbook. Apparently, there is limited research on "the effectiveness of such actionable links on students' learning experience and success" as stated by Iraj et al. [22]. The authors also warned that most students appear to lack "feedback literacy" and may only respond to quality feedback. This research project aspires to provide an informative contribution in this regard by using Moodle Quiz module's overall feedback

feature, which can provide different feedback for a different level of quiz performance.

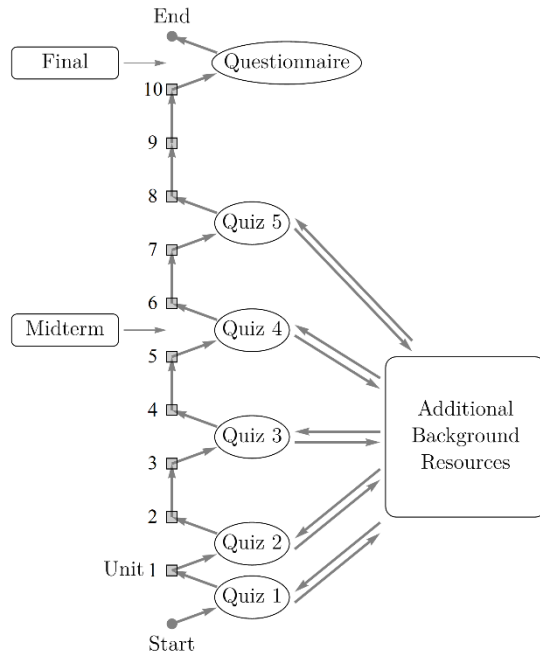

Figure 2. Learning path and checkpoints in the online physics course.

4.2 LMS Log Data

The LMS automatically records the date, time, and score of each checkpoint quiz and keeps track of other learning activities, including recommended learning objects accessed by individual students. When combined with the timing and marks achieved on assignments, lab reports and exams, each student's progress throughout the course materials can be highlighted. Such information allows us to look for patterns of effective learning behaviour and explore the effectiveness of the proposed adaptive feature on the student's academic achievement in the course.

4.3 Student Self-Reflection Questionnaire and Faculty Feedback

The effectiveness of the course content and design, in addition to the student's learning behaviour, is also gauged through a self-reflection questionnaire completed by the student toward the end of the course. The questionnaire is conducted online and consists of a mix of multiple-choice and written response questions. The collected data provides self-reflection by the students on their study behaviour, feedback on the proposed adaptive feature, convenience of course design, and effectiveness of course content, especially the interactive exercises and dynamic diagrams. Also, we will solicit qualitative assessment and feedback from instructors and tutors about the efficiency and effectiveness of the system through interviews.

4.4 Data Analysis

Based on the results of the first three checkpoint quizzes (see Figure 2), we group students by score quartile (students who perform below 25%; students with a score between 25% and 50%; students with a score between the 50% and 75%; and the students who score above 75%.) We then follow the learning behaviour of each group and their performance on the midterm examination. The fifth group of students who choose to skip the checkpoint quizzes,

continuing from one unit to the next, can act as a reference group. A similar analysis is repeated for data collected during the second half of the course.

To compare the use of recommended learning resources across quartiles, we compute the mean number of resources accessed for each quartile. We hypothesize that students with higher exam scores tend to engage more seriously with feedback and follow a more regular study pattern (i.e., suggested study schedule) than those with lower exam scores. We will see if the response to feedback between student groups is significant at the $p < 0.05$ level for different quizzes. The findings can be used to detect struggling students since they are less likely to use exercise for study purposes. Also, we conjecture that the students with the lowest grades have the lowest score on checkpoint quizzes and follow a more random study pattern. Their learning behaviour may be guessing or viewing hints in an attempt to build a catalog of correct answers, rather than actively using their knowledge to correctly address their knowledge gaps and adopt a more productive learning behaviour.

5. CONCLUSION

Students' interaction with the course materials, combined with their use of personalization through checkpoint quizzes, the results of self-reflection questionnaires, and peer faculty feedback, are analyzed in association with student's performance on assignments, lab reports and exams. The purpose is to look for educationally meaningful information regarding effective personalized feedback, successful learning behaviour, and good aspects of instructional design. An extension to this project would involve investigating the impact of personalizing the study schedule on the issue of procrastination and student attrition in online physics courses.

ABSTRACT

As scientific writing is an important 21st century skill, its development is a major goal in high school science education. Research shows that developing scientific writing skills requires frequent and tailored feedback, which teachers, who face large classes and limited time for personalized instruction, struggle to give. Natural Language Processing (NLP) technologies offer great promise to assist teachers in this process by automating some of the analysis. However, in Hebrew, the use of NLP in computer-supported writing instruction was until recently hindered by the lack of publicly available resources. In this paper, we present initial results from a study that aims to develop NLP-based techniques to assist teachers in providing personalized feedback in scientific writing in Hebrew, which might be applicable to other languages as well. We focus on writing inquiry reports in Biology, and specifically, on the task of automatically identifying whether the report contains a properly defined research question. This serves as a proof-of-concept of whether we can build a pipeline that identifies major components of the report and match them to a predefined grading rubric. To achieve this, we collected several hundreds of reports, annotated them according to a grading rubric to create a supervised data set, and built a machine-learning algorithm that uses NLP-based features. The results show that our model can accurately identify the research question or its absence. To the best of our knowledge, this is the first paper to report on the application of Hebrew NLP for formative assessment in K-12 science education.

Keywords

Scientific writing, Formative assessment, Natural Language Processing

1. INTRODUCTION

Writing is a critical 21st century skill, and a high level of writing proficiency is required to succeed in academia and workplaces [1]. In science, writing is one of the primary

means of communication in the scientific community and a crucial aspect of scientific literacy. Thus, developing writing skills has become a major educational goal in high school science education [11].

Numerous studies have shown that developing scientific writing skills among high school students poses considerable difficulties for both students and teachers [9, 15, 23]. A lot of this may be due to the lack of formative feedback, which is known to be essential for the development of these skills [17, 10]. Formative feedback aims to guide and improve students' learning by providing them with information about the gap between their current and the desired performance. In the context of formative feedback on scientific writing, it has been shown that in order to support students in improving the quality of their writing, the formative feedback needs to be personalized and specific [3, 14]. It should also provide applicable recommendations for improvement, and explanations as to why such improvements are needed [16].

Proper writing instruction demands a significant amount of time from teachers, for preparing materials, reading, editing, and providing feedback. The educational reality is that teachers are faced with large class sizes that limit their ability to find the necessary time to devote to this process, resulting in a considerable delay in the feedback that students receive, and in its quality [1]. Another challenge is designing guidance that motivates students to engage in substantial writing revisions. Consequently, revising written explanations based on personalized guidance rarely occurs in science classrooms [19].

Technology holds much promise for improving this process, by supporting teachers in providing formative assessment. Automated computer scoring systems are being developed in order to address the challenges of assessing students' writing (e.g., [22, 19, 21, 18, 12, 20]). Among these, automated essay scoring technologies can enhance both large scale assessment and classroom instruction [3], as they have many advantages in the fields of assessment and instruction including objectivity, standardization and efficiency [5]. However, these technologies were mostly employed for *summative*, rather than *formative*, purposes [21].

In addition, while automated supporting tools for revising texts on the micro-level (such as grammar and spelling) are well represented [18], tools that support the development of writing strategies including self-monitoring and improving

Moriah Ariely, Tanya Nazaretsky and Giora Alexandron "First Steps Towards NLP-based Formative Feedback to Improve Scientific Writing in Hebrew" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 565 - 568

macro-level of text quality (such as argumentative structure and rhetorical moves) are infrequent [18]. In the transition from essay scoring to writing instruction, feedback design is of great importance, since it is the primary means through which students can evaluate and improve their writing [17].

In Hebrew, the use of NLP in computer-supported writing instruction was until recently hindered by the lack of publicly available resources. Hebrew is a morphologically rich language (MRL). It is complex, characterized by a highly productive inflectional morphology, with prefixes, suffixes and circumfixes, and also nouns, adjectives and numerals inflections for number (amount) and gender [8]. Following recent developments in Hebrew NLP, the high-level goal of our research is developing NLP-based techniques to assist teachers in providing personalized feedback in scientific writing in Hebrew, which might be applicable to other languages as well.

The task that we study is writing scientific reports in inquiry projects in Biology. A fundamental component of the report is a well-formulated research question(s). Formulating research questions that can be answered empirically is one of the practices needed in order to become scientifically literate [11]. In fact, by ‘composing questions’, students attend to the main ideas and check if the content is understood [13]. Since the research questions are defined on the early stages of the project, failure to properly define them can have a long-term effect on the quality of the project and report.

With this rationale in mind, we focus on studying NLP-based means to provide personalized feedback on the quality of the questions that students define. A precondition for an automatic assessment of the quality of the research questions is detecting them automatically in the text. The identification of the research questions in students’ essays serves as a proof-of-concept (POC) for learning a formative assessment grading scheme for major components of the report.

Our work is the first step towards NLP-based tools that will support K-12 science educators in teaching and assessing scientific writing in Hebrew. To the best of our knowledge, there is no published work on NLP-based formative assessment in Hebrew, and this research has the potential to pioneer this exciting domain.

2. METHOD AND RESULTS

This section describes the experimental setup, how the data was collected and annotated, the NLP pipeline and features, the machine learning algorithm, and the results.

2.1 Research context

Over 20,000 high-school students in Israel major in biology each year [4]. The Israeli Biology curriculum includes an inquiry project that constitutes 30% of the final grade [7]. It is conducted collaboratively in groups of 2-3 students. The students conduct an inquiry on a biological issue, ask research questions, design and carry out an experiment, collect data, and analyze it. Students are required to document their work in a scientific report. Within this process, the writing task was reported by teachers and students to

be the most challenging part [6]. It is an iterative process, which often takes up to 10 iterations to complete.

2.2 Data Collection

The data include 705 scientific reports, collected from 520 student groups that belong to 33 classes.

The reports are submitted in Hebrew as Word documents. In the first phase of the project the Introduction part, which is where the research question should be defined, was separated from the rest of the text. The Introduction typically consists of 2-5 pages. Well-written introduction section should contain the following discourse categories:

- Biological process.
- Research question. One research question if the work is submitted by two students, two research questions if the work is submitted by a group of three students.
- Research hypothesis.
- Description of the organism.

Following is an example of a typical well-written research question: "Our research question is how does alcohol concentration influence cell respiration rate in yeasts".

2.3 Creating a supervised data set

In order to create a supervised data set that can be used as an input to the machine learning algorithm, we annotated students’ texts. The goal of the annotation was to mark the segments of the texts that represent the aforementioned four discourse categories. The relevant parts of the texts were encoded with <tagname> and </tagname> tags that preceded/succeeded the relevant segments. For example, each research question was preceded with an <rq> tag, and succeeded by an </rq> tag, which were inserted into the text. The annotation was performed at a sentence or multiple sentences level. Each sentence was labeled with at most one discourse category. Our annotation scheme does not allow overlapping of the categories, but the same category may appear multiple times (e.g., two different research questions). We note that the majority of the sentences do not belong to any category and are not labeled at all.

The process was conducted by two domain experts (including one of the authors). The experts first created a grading rubric and then tagged the texts accordingly. In the first stage of the annotation process, both judges worked together to create a protocol for detecting the discourse elements in the text. Next, they worked independently to label 147 texts (from 44 student groups that belong to 6 classes), and the resulting labels were discussed until disagreements were resolved. Finally, additional 56 texts were labeled by one of the experts.

To create a training and test sets we chosen randomly one report from each student group, so the chosen reports represent different stages of report readiness. This means that some of the reports do not contain research questions at all and some research questions are ill defined. In total, the data set includes 100 texts containing 5513 sentences and 197 research questions.

2.4 Research Question identification

We consider the task of research question identification as a sentence-level classification task. Each sentence is classified as a research question or not. The data set was divided into training and test sets, as presented in Table 1.

Table 1: A summary of the annotated data.

	Number of texts	Number of sentences	Number of research questions
Training set	70	4013	139
Test set	30	1500	58
Total	100	5513	197

One of the challenges is that the data set is highly imbalanced. The ratio between examples in the minority class (research question sentences) and the majority class (non-research question sentences) is less than 1:25. Thus, a naive classification algorithm returning a negative answer for all the sentences will achieve 96.4% accuracy, but it is of no practical value. To evaluate the goodness-of-fit of our algorithm, we use the following measures:

- Precision = $\frac{TruePositive}{(TruePositive+FalsePositive)}$
- Recall = $\frac{TruePositive}{(TruePositive+FalseNegative)}$
- F-measure = $\frac{2 \times Precision \times Recall}{Precision + Recall}$

2.5 Parsing and feature engineering

2.5.1 Parsing

We use the Hebrew morphological parser developed by the National Institute for Testing and Evaluation (NITE) [2]. It is used to resolve morphological and parts of speech (POS) disambiguity. The reported accuracy of the NITE parser is 90% for the full morphological analysis and 95% for POS analysis.

Running the parser on the annotated student texts generates a tab-separated value file. Each row in the file corresponds to one word in the text, and contains the following information:

- isResearchQuestion: *True/False* - indicates whether the word is part of a research question sentence
- word original form: the word as appears in the text
- word basic form: the base form of the word
- POS: part of speech of the word

2.5.2 Bag of Words and feature set

First, we construct a Bag of Words (BOW) dictionary as follows:

1. Divide the data set randomly into training and test sets as presented in Table 1.
2. Build a BOW dictionary containing the basic form of each word that appears at least three times in a research question text segment (within the training set), and its corresponding POS.
3. Remove stop words: numbers, punctuation marks except for question mark, prepositions, pronouns, auxiliary verbs, all forms of the word "the" (could appear in a number of forms in Hebrew)

Then, for each sentence in the data set, we compute the following set of features:

- We introduce a feature for each BOW dictionary entry. The value of the features is defined as the number of appearances of the corresponding dictionary entry in the sentence.
- In addition, human experts composed a list of phrases that can be used as markers for a research question, such as "what is the connection", "what is the relation", etc. (in Hebrew, due to word agglutination, these phrases consist of two words only). We introduce an additional Boolean feature to represent the appearance of any of these phrases.

2.6 Results

We used the training set to train three types of classifiers: SVM, Logistic regression, and Naive Bayes. Their performance, computed over 500 5-fold cross-validation iterations, is presented in Table 2 (mean values). The best performance was achieved by the Logistic Regression classifier. To evaluate the performance on unseen data, we then trained a logistic regression classifier on the entire training set, and measured its performance on the test set. The results are presented in Table 3.

Table 2: The results of 500 5-fold cross validation runs on the training set

	Precision	Recall	F-measure
Logistic Regression	86.9%	74.3%	79.9%
SVM	75.9%	77.3%	75.9%
Naive Bayes	62.0%	88.6%	72.8%

Table 3: The results of the Logistic Regression model on the test set

	Precision	Recall	F-measure
Logistic Regression	84.2%	94.1%	88.9%

To understand the source of the errors we examined the sentences missed by the classifier. The main source of the errors is related to the failure of the parser to treat correctly a point sign '.' inside Latin names of organisms (e.g., 'E. Coli', 'St. Albus'). As a result, sentences containing such names were considered by mistake as two separate sentences and the classifier failed to identify them as a research question.

3. NEXT STEPS

Next, we plan to extend our model to identify the internal structure of the research question, as defined in the grading rubric. To support this step, the annotation scheme was extended to identify the required components of the research question: *opening* (e.g., "Our research question is:"), *independent variable* (e.g., ethanol concentration), *dependent variable* (e.g., cellular respiration rate), *connection between the variables*, and *organism* (e.g., bacteria, yeast). As this rubric is designed to be the basis for generating formative feedback, the experts gave a score (0-2) to each of these components, as well as an additional score for the *location* of the entire sentence in the text. This scheme was applied to 115 texts in a process similar to the one reported in Subsection 2.3. We also used the texts to create synthetic examples. In case the final version of a particular report was not well-written, the judges fixed the writing and inserted

the fixed version as an additional example. In total, 32 additional examples were created in this manner.

Based on this, we intend to create a computational model for identifying the internal structure, and use it to conduct an intervention study, in which students will receive formative feedback that is based on the computational analysis of the research question structure. In parallel, we will extend our method to the identify the remaining three discourse categories (biological process, research hypothesis, and description of the organism).

4. CONCLUSIONS

This paper presents preliminary results from a study that aims to develop NLP-based tools to assist teachers in providing formative feedback on scientific writing in Hebrew. Specifically, we demonstrate that our model can accurately identify the *research question* (or its absence), which is a key component of the specific writing task that we study (scientific report of inquiry project in Biology). Our results, although very preliminary, are a first step towards using NLP to provide formative assessment on scientific writing in Hebrew. To the best of our knowledge, there is no prior work that applies Hebrew NLP to provide formative feedback in K-12 science education.

5. ACKNOWLEDGMENTS

The authors thank Cipy Hofman and Yona Dolev for their contribution, and the National Institute for Testing and Evaluation (NITE) for providing access to the Hebrew morphological parser, and for partially funding this project. This research is supported by The Willner Family Leadership Institute for the Weizmann Institute of Science, Iancovici-Fallmann Memorial Fund, established by Ruth and Henry Yancovich, and by Ullmann Family Foundation.

ABSTRACT

Nowadays, students prefer to complement their studies with online video materials. While there are many video e-learning resources available on the internet, video sharing platforms which provide these resources, such as YouTube, do not structure the presented materials in a prerequisite order. As a result, learners are not able to use the existing materials effectively since they do not know in which order they need to be studied. Our aim is to overcome this limitation of existing video sharing systems and improve the learning experience of their users by discovering prerequisite relationships among videos where basic materials are covered prior to more advanced ones. Experiments performed on commonly used gold standard datasets show the effectiveness of the proposed approach utilizing measures based on phrase similarity scores.

Keywords

prerequisite extraction, prerequisite graph, prerequisite

1. INTRODUCTION

With the widespread adoption of computers, especially among the young generation of students, and the video sharing platforms (VSP) such as YouTube, learners are more and more using video materials. In fact, there are many VSPs publishing learning material which are rich in content and very popular among students. The video lectures of the Physics Professor Walter Lewis¹ at MIT having millions of views in YouTube are an example of this paradigm shift.

Learning materials published on VSPs are not treated differently than other types of videos since these platforms are not designed to be used as an e-learning system. Therefore they do not present the materials in a structural manner following the prerequisite relationships. VSPs follow their users to

bring the most relevant personalized material, but these are not determined based on the background of their users, but just their interests. Therefore, the presented list of materials does not follow the prerequisite order. Our aim in this work is to overcome this limitation of existing VSPs by organizing the videos according to a prerequisite order, such that prerequisites are recommended to be watched prior to the actually searched material. This way we intend to improve the learning experience.

Our methodology is based on structuring the video learning materials using prerequisite relationships where basic materials are covered prior to more advanced ones. This is an offline process implemented as a separate module which can be integrated into any VSP providing an API with search capabilities. Given a predefined set of concepts, we first collect the video learning materials related to those concepts and extract their subtitles. We then build a model to infer prerequisite relationships based on the collection of subtitles. VSPs return a list of videos, where videos are ranked based on their relevance with respect to the search term. Our unsupervised methodology exploits the powerful relevance ranking models of the VSPs by incorporating the returned alternative materials in prerequisite relationship extraction. We implemented the proposed methodology using YouTube as a VSP. Experiments performed on concepts from a benchmark data set show that the proposed method utilizing measures based on similarity scores identifies the prerequisite relationships among those concepts and therefore provides users with a better learning experience.

2. RELATED WORK

Our related work is described in two main areas in the following subsections.

2.1 Prerequisite detection

The task of identifying prerequisite relationships between concept pairs was first introduced in [12] and existing methods that address this problem are based on supervised learning. One popular and important feature in this context is called reference difference (RefD) [3] which intuitively captures prerequisite relationships between concepts A and B by counting how often B refers to A and how often A refers to B . If B refers frequently to A , but A does not refer often to B , one may infer that B is a prerequisite for A . The original RefD feature relies on the hyperlink structure within documents, which is the reason for computing RefD based

^{*}Corresponding author

¹<https://www.youtube.com/watch?v=sJG-rXBmCc>

on Wikipedia articles. In addition to RefD, previous works [13, 8] extended the list of features derived from Wikipedia articles, e.g. by including related, but more abstract articles. In [6] word embeddings of texts are used as features besides 16 other features like RefD to represent text documents for prerequisite detection. Interestingly, RefD turned out to be consistently the most important feature across different languages and datasets, which motivates our choice for focusing on adapting RefD to unstructured video subtitles. In [1] a method is presented, which combines burst analysis and co-occurrence of words to identify prerequisite relationships. This approach uses unstructured text from books as input and it requires only light training as parameters need to be set based on the dataset, otherwise it relies on the default values. Unlike all previous methods, our method is fully unsupervised by nature. It relies on the core idea of RefD to determine prerequisite relationships, but in contrast to existing methods that exploit links in structured documents, we use exact matches to count how often concepts occur in unstructured text documents as noun phrases. Moreover, our approach could easily be integrated into the existing supervised methods as a feature.

2.2 Resources for extracting prerequisite relationships

In the past, different resources were used for identifying prerequisite relationships, namely text books [13, 4, 1], course prerequisites and video playlists [10], Wikipedia [12, 3, 5], a mixture of Wikipedia and video subtitles [8], and the Wikipedia clickstream [11]. Wikipedia has been the most popular resource as RefD relies on the structured information present in Wikipedia articles, e.g. links to related or more abstract concepts. But Wikipedia has multiple limitations as a resource. First, there might be no Wikipedia article for certain concepts [7]. Second, the desired concept might be part of a larger Wikipedia article which implies that some of the information is too broad or that concept simply cannot be found unless one knows the specific article in which that concept was mentioned. However, the most important limitation of Wikipedia in the context of e-learning is the fact that a concept is explained from a single perspective instead of multiple ones, which is important considering that individuals learn differently and might thus understand alternative explanations more easily. For these reasons, we opt in this paper for a VSP, YouTube in our case, as a resource for concepts since there are typically multiple videos available for a specific concept, potentially explaining it from different perspectives which benefits individuals as everyone learns differently. More precisely, we retrieve the subtitles of videos similar to [8], but in contrast to them, we collect a set of videos per concept instead of a single one per concept. Our approach is also different from [10], who utilize the downloaded video subtitles for creating bag-of-word representations to infer the hidden concepts using LDA and one video exists per concept.

3. MOTIVATION AND PROBLEM DEFINITION

As mentioned in Section 2.2, there may be no Wikipedia article available for a specific concept. Then any features including RefD relying on such structured text documents cannot be computed. For example, Wikipedia has no entry

for the concept "Recursive Backtracking" from our dataset (cf. Section 5.1), there is only an article related to the general concept of "Backtracking". Therefore, we extract the video subtitles and use them as text documents describing the concepts explained in the videos. Another advantage of using a VSP is that videos related to a concept explain the concept from different perspectives, with a varying level of detail. VSPs such as YouTube have powerful relevance ranking and diversification algorithms which we indirectly incorporate in the RefD score calculation by including the subtitles from the list of videos returned for a concept.

We model our problem with strictly partially ordered sets. Given a set of m concepts $C = \{c_1, \dots, c_m\}$ and a set of n videos associated with each concept, $V = \{v_{i,1}, \dots, v_{i,n}, \dots, v_{m,1}, \dots, v_{m,n}\}$, we extract from all collected videos related to a concept c_i , namely $\{v_{i,1}, \dots, v_{i,n}\}$, the subtitles and merge them into a text document t_i , such that each concept c_i is represented by a single text document t_i in the set $CT = \{(c_1, t_1), \dots, (c_m, t_m)\}$. From CT we form a strictly partially ordered set PO-CT by introducing the binary prerequisite relationship $Preq((c_i, t_i), (c_j, t_j))$ between c_i and c_j , where $c_i, c_j \in C$ and

$$Preq((c_i, t_i), (c_j, t_j)) = \begin{cases} 1 & \text{if } c_i \text{ is a prerequisite for } c_j \\ 0 & \text{otherwise} \end{cases}$$

Therefore, PO-CT is transitive (if c_i is a prerequisite for c_j and c_j is a prerequisite for c_k , c_i must also be a prerequisite for c_k), asymmetric (if c_i is a prerequisite for c_j , c_j cannot be a prerequisite for c_i), and irreflexive (c_i cannot be a prerequisite for itself) by definition [2]. Our final goal is to construct an acyclic prerequisite graph PG visualizing the prerequisite relations from PO-CT.

4. PREREQUISITE DISCOVERY PROCESS

Our method for building the prerequisite graph PG comprises two phases. In the first phase, we compute the strength of the pairwise prerequisite relationships which will be stored in a prerequisite matrix. Some of the relationships will violate the assumptions made for a partially ordered set, due to the pairwise computation of prerequisite relationships. For example, if $Preq((c_i, t_i), (c_j, t_j)) = 1$, $Preq((c_j, t_j), (c_k, t_k)) = 1$, $Preq((c_k, t_k), (c_i, t_i)) = 1$, then there would be a cycle of prerequisite dependencies as c_i would be a prerequisite for c_j , c_j would be a prerequisite for c_k , and c_k would be a prerequisite for c_i , which needs to be resolved. Therefore, in the second phase for graph construction, we use heuristics to overcome these issues.

4.1 Prerequisite Score Calculation

Determining if there is a prerequisite relationship between two concepts c_i and c_j implements the core idea of RefD, namely that if c_j occurs rarely in the text document t_i describing c_i , but c_i occurs frequently in the text document t_j representing c_j , then c_i is most likely a prerequisite for c_j . Unlike RefD, t_i and t_j do not contain related concepts to c_i and c_j , but rather describe only the concepts c_i and c_j . Since we compare text documents, we do not require any structured information such as links to related concepts. By gathering n number of videos for each of the concepts c_i and c_j from a VSP, our function $Preq()$ exhibits irreflexivity and asymmetry. We compute $Preq((c_i, t_i), (c_j, t_j))$ as follows:

1. Set input parameter - n : number of videos to collect per video for a concept
2. Given a pair of concepts c_i and c_j , retrieve the n most relevant videos for each of the concepts c_i and c_j from a VSP; extract their subtitles and merge those of $\{c_{i,1}, \dots, c_{i,n}\}$ into text document t_i and those of $\{c_{j,1}, \dots, c_{j,n}\}$ into t_j yielding (c_i, t_i) and (c_j, t_j) , respectively. t_i and t_j describe the concepts c_i and c_j in detail.
3. Preprocess t_i and t_j and create two lists L_i and L_j which contain all of the nouns and noun phrases from t_i and t_j , respectively. This step is performed since concepts occur in text documents always as nouns or noun phrases.
4. For each noun and noun phrase in L_i , count the exact matches with c_j and store it in a variable called $counts_j$.
5. For each noun and noun phrase in L_j , count the exact matches with c_i and store it in a variable called $counts_i$.
6. The output of the prerequisite relationship calculation is $w_{i,j} = counts_j - counts_i$
7. $RefD((c_i, t_i), (c_j, t_j)) = w_{i,j}$
8. Store $w_{i,j}$ in the score matrix W

The score matrix W has the following shape:

$$W = \begin{pmatrix} w_{1,1} & \cdots & w_{1,m} \\ \vdots & \vdots & \vdots \\ w_{m,1} & \cdots & w_{m,m} \end{pmatrix}$$

where $w_{i,j}$ corresponds to the prerequisite score between the concepts in the i -th row and the j -th column. Note that $w_{i,i}$, i.e. all elements on the diagonal, are zero due to the irreflexivity property of RefD. Moreover, $w_{i,j} = -w_{j,i}$ due to RefD being asymmetric. Due to this property, we have to compute $RefD((c_i, t_i), (c_j, t_j))$ only $m * (m - 1) / 2$ times. We also note that the output of RefD can be converted into a binary output as follows: If $w_{i,j} < 0$, c_i is a prerequisite for c_j and the strength of the prerequisite relationship is $|w_{i,j}|$. Otherwise c_j is not a prerequisite for c_i . In other words,

$$Preq((c_i, t_i), (c_j, t_j)) = \begin{cases} 1 & \text{if } w_{i,j} < 0 \\ 0 & \text{otherwise} \end{cases}$$

Therefore, $RefD((c_i, t_i), (c_j, t_j))$ approximates the binary relationship $Preq((c_i, t_i), (c_j, t_j))$.

4.2 Prerequisite graph construction

Given the score matrix W from Section 4.1, we want to construct the acyclic prerequisite graph PG where concepts correspond to nodes and directed edges from concept c_i to c_j with weight $w_{i,j}$ are added. However, since $RefD((c_i, t_i), (c_j, t_j))$ is a heuristic to approximate $Preq((c_i, t_i), (c_j, t_j))$, errors are introduced and PG constructed from W is not necessarily acyclic yet. For example, suppose that from the

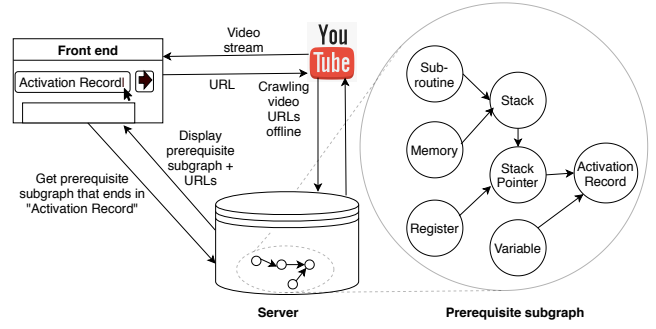

Figure 1: Client server architecture of our learning platform. Adapted from [9]

first phase, given three given concepts, a, b, c , we obtained the following matrix W :

$$W = \begin{pmatrix} 0 & x = -0.2 & -z = 0.2 \\ -x = 0.2 & 0 & y = -1.0 \\ z = -0.2 & -y = 1.0 & 0 \end{pmatrix} \quad (1)$$

The entries in W (cf. 1) correspond to the weights $x = w_{a,b}, y = w_{b,c}, z = w_{c,a}$, respectively. This matrix results in a PG with a cycle because a is a prerequisite for b (since $x < 0$), b is a prerequisite for c (since $y < 0$), and c is a prerequisite for a (since $z < 0$). To remove cycles, we apply to W the following method. Concept c_i , which is stored in the i -th row of W , is only connected to the prerequisite with the highest absolute weight $w_{i,j}^*$ in row i . If all weights are zero in row i , c_i has no outgoing edges. This way the most powerful prerequisite relationships are preserved.

This method only prevents cycle formation in the graph, but still allows to model scenarios like one concept being a prerequisite for multiple concepts or multiple concepts being prerequisites for a single concept. However, PG might still contain redundant edges after applying our method. For example, assume that we swap the weights of z in W (cf. 1), so $z = 0.2$ and $-z = -0.2$. Then our method results in a being a prerequisite for b and c , while b is a prerequisite for c . Now c is directly reachable from a , but also from a over b . To remove such redundant edges, we compute the transitive closure of the acyclic PG using Warshall's algorithm. The resulting PG can then be visualized.

4.3 Architecture and Implementation

We are in the process of integrating the methods described in Section 4 into our e-learning platform which uses YouTube videos as video learning materials. The platform is built on top of Open edX². In the context of the e-learning platform, the prerequisite relationships are extracted offline given a set of concepts, which allows us to construct the prerequisite graph PG from the score matrix W . A small sample PG is depicted on the right-hand side in Fig. 4.3 for the domain "Operating Systems". For example, to understand the concept "Activation Record", it is assumed that a learner knows about "Stack" and all the other concepts shown in the graph. Therefore, learners may only start "Activation Record" once they completed all prerequisites.

²<https://github.com/edx/edx-platform>

The rest of the client server architecture of our e-learning platform is depicted in Fig. 4.3. Initially, a set of concepts is automatically extracted from text documents such as books or slides according to [13]. URLs of video learning materials are then extracted from YouTube, together with the pairwise prerequisite relationships between the concepts based on the subtitles. Whenever a learner wants to study a concept, she submits a query through the front end, e.g. "Activation Record", and the query is then transferred to the server for processing. The server queries PG to return the subgraph which contains the requested concept and its prerequisites as a list of JSON objects, where each concept contains additional metadata like URLs to multiple YouTube videos and which of those should be recommended to be watched first by the learner, i.e. their rankings.

5. EVALUATION

The resulting PG depends on the quality of the identified prerequisite relationships. Therefore, for experiments we analyze the performance of our approach described in Section 4.1 in terms of how well it identifies prerequisite relationships according to the first phase of our methodology.

5.1 Datasets

For the experiments we used Metacademy³, which provides concepts for particular domains together with the prerequisite relationships among these concepts. Prerequisite relationships were annotated manually by experts of Metacademy. We focus on the domain "Data Structures & Algorithms" in our experiments which is comprised of 30 concepts from which we replaced three of them by three alternative ones that were listed as prerequisites for some of the concepts, but not included in the dataset. The main reason for this decision is due to them covering aspects of topics that are already included. From these 30 concepts, we randomly select 43 positive prerequisite relationship pairs for our experiments. In line with previous approaches [6, 8], we evaluate our method on a balanced dataset. Thus, we also generate 43 negative pairs by combining concepts that have no prerequisites in common. For each of the 30 concepts we retrieved the first n videos from YouTube and merged them into a single text document per concept, where $n = 1, \dots, 20$.

5.2 Performance for Prerequisite Detection

Our baseline method extracts the subtitles from a single video, whereas all other methods rely on merging the subtitles of multiple videos for a concept. We analyze how precision, recall, and F1-score of our proposed method are affected by varying n , the number of considered videos per concept c_i from which the subtitles are extracted to form the corresponding text document t_i .

The results are shown in Fig. 5.2. In terms of F1-scores, we observe that they gradually increase from 0.46, when using only subtitles of a single video per concept, up to 0.75 when incorporating subtitles from up to 20 related videos for a concept. Especially in the beginning, when using less than six videos per concept for subtitle extraction, adding more videos improves the F1-scores noticeable. But how does varying n affect precision and recall? Depending on

³<https://metacademy.org/browse>

Figure 2: Influence of n , the number of considered videos per concept to be used for extracting subtitles, on the performance of our method.

the application, one of the two metrics might be more important. Fig. 5.2 indicates that precision slightly declines from 1.0 to 0.9 when considering more than 10 videos before stabilizing. However, at the same time recall roughly doubles from 0.3 to 0.65 when considering the 20 most relevant videos compared to using only a single video. Overall, the experiment suggests that including multiple videos per concept yields a more accurate detection of prerequisite relationships compared to using a single video per concept. One possible explanation for this increase in recall is that by including a larger number of videos, we also include a richer vocabulary as different educators prefer different terms. This, in turn, benefits the exact matches used in our method for detecting prerequisite relationships. One might even argue that this roughly corresponds to the idea of querying related Wikipedia articles instead of limiting one's computations to the Wikipedia articles describing the respective concept. However, this observation from our experiments might be an artifact and not hold for other domains and thus we cannot rely on this effect.

6. CONCLUSION

In this paper we have demonstrated that we can detect prerequisite relationships among video learning materials based on their subtitles using an unsupervised approach by utilizing the core idea of the well-known RefD metric with exact matches of concepts in subtitles that were collected from videos. Using only this indicator alone to determine prerequisites shows its effectiveness. This implies that our method could also be incorporated as a feature into supervised approaches to improve their performance.

One limitation of our proposed method is that it relies on exact matches and therefore ignores synonyms and semantically related terms that describe similar concepts. Therefore, it seems promising to support fuzzy matches in our method. One idea would be to employ word embeddings to that end in a similar fashion as described in [8]. Moreover, we have evaluated our proposed method only on a single domain thus far, but we plan to assess the performance on additional datasets from different domains. We hope our methodology of identifying the prerequisite relationship among video learning materials and presenting their related materials accordingly will improve the learning experience of students.

A method for generating features representing the students' degree of anticipation/delay to complete assignments

Francisco Cervera-Mercadillo,

juanalfonso.lara@udima.es

ABSTRACT

Some current methodologies stress the importance of continuously assessing the students to check their progress, instead of having an only final examination. To do so, several learning resources are presented to the students, so they can complete different actions over those resources at certain particular dates. This scenario presents a good chance for research since it might be useful to analyze the point up to which students complete in time the tasks they are supposed to do. In this paper, we present a method that takes raw log Moodle data and generates new features that represent the degree of anticipation/delay of students when completing the tasks suggested by their tutor. We have developed a system that implements this method obtaining some minable sights that preliminarily seem to be useful to predict phenomena such as academic dropout. Obviously, future deep experiments must be conducted to demonstrate the validity of those new features.

Keywords

Data preprocessing; E-learning; Continuous Assessment; Assignment-related temporal features; Moodle.

1. INTRODUCTION

In the last years, new formative paradigms such as E-learning (Electronic Learning) have emerged in order to provide people with ubiquitous learning [1]. E-learning platforms like Moodle provide useful data about students' behaviors that can be exploited by Educational Data Mining (EDM) or Learning Analytics (LA) techniques [2].

Many current education initiatives are based on continuous assessment during the courses. It means that students are encouraged to complete different assignments at certain suggested dates [3]. Some of those students will complete those assignments at the suggested date, others will do it earlier and some of them may complete it late.

In this paper, we present a method that takes Moodle logs from a particular course and a list of suggested dates where assignments are suggested to be completed by the students according to the

tutor recommendation and generates a minable sight in the form of a table containing as many rows as students enrolled in the course and as many columns as assignments or tasks that students should carry out. Each cell will take an integer value representing the degree of anticipation or delay for the particular student (row) to complete each task (column) suggested by the tutor. These new features can be useful in the prediction of the students' performance, which is one of the main goals of EDM.

Although there is some literature on procrastination [4], to the best of our knowledge, it is the first time that the high-level features we propose have been used in EDM field so our ideas may represent an interesting line of research, which is the main contribution of this paper.

The rest of this paper is organized as follows. Section 2 presents a brief description of the proposed method. Section 3 contains a technical description of the implemented tool and the preliminary results obtained. Finally, Section 4 includes a discussion of the results and conclusions obtained, as well as some potential future lines of research.

2. METHOD

In this paper, we propose a method that intends to generate new features from Moodle logs that represent the degree of anticipation or delay for each student to complete the tasks proposed by the tutor in order to reach the formative results supposed to acquire during continuous evaluation.

Those suggestions may be really diverse and include tasks such as reading a document, watching a video, taking part in a forum or submit a report. In particular, we have defined a series of potential kinds of tasks that the students can carry out with educational resources uploaded to the Moodle virtual classroom by the tutor. Those are: View, Create, Update, Delete, Subscribe, Review, Submit, and Start. For each educational resource and type of task, the tutor has to define a reference date when the students are supposed to complete that task on the respective resource (Table 1).

The proposed method intends to take raw Moodle data and generate a new feature for each resource and type of task in a way that each new attribute will take negative values for "eager" students, positive values for "late" students, and 0 values for students who complete their tasks exactly the same day as the tutor suggested.

This method is intended for EDM/LA experts who intend to use these kinds of features in order to analyze their impact on students' performance. Note that our method starts from Moodle

Francisco Cervera and Juan Lara "A method for generating features representing the students' degree of anticipation/delay to complete assignments" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 574 - 577

log data that register all the events (actions) carried out by the students on each resource of the Moodle platform.

Table 1. Excerpt of an example of suggested tasks and dates

Computer Architecture Course	
<i>Week 1</i>	
Task	Suggested Date
View the Presentation Session (VPS)	8-Oct-2019
Read the Teaching Guide (RTG)	13-Oct-2019
<i>Week 2</i>	
Task	Suggested Date
Subscribe to Doubts Forum (SDF)	14-Oct-2019
Visualize Unit 1 PDF Document (VU1)	16-Oct-2019
Submit the report of Activity 1 (SA1)	20-Oct-2019
...	...

We have also defined our approach in a way that the expert can perform the following tasks to particularly design his/her data analysis:

1. Student selection (focus only on some certain students).
2. Period selection (focus only on certain time intervals of the course).
3. Resource selection (only consider some educational resources).
4. Task type selection (only consider some types of actions for each resource).
5. Reference dates definition (define, for each selected resource and type of action).
6. Generate new attributes' values (for each selected resource, type of action and student).
7. Manually add the class attribute for the latter analysis (dropout, pass/fail, ...).

That would lead to a minable sight for predictive purposes with the newly generated features. Table 2 shows an example.

Table 2. Excerpt of an example of generated minable sight for academic dropout prediction

<i>Student_n</i>	+1	0	+2	-1	0	...	0

3. IMPLEMENTED SYSTEM AND RESULTS

In this section we will explain the main aspects about the design of the system (3.1), how the system works (3.2) and system outputs (3.3).

3.1 Design and Technical details

The system was designed in order to meet four important main objectives:

1. The implemented method should guide the user step by step, executing the different tasks developed as an assistant, to finally obtain the desired minable view.
2. Due to the problem of dealing with large volumes of records to be processed, data persistence was decided not to be necessary. In our case, preprocessing the data in memory helped speed up the application of the different data selection, cleaning and transformation techniques.
3. During the development of the application, it was intended to design a system focused on usability, in order to facilitate the learning and use of the tool by the end-user.
4. It was necessary to define a properties file so the user could define some parameters difficult to provide a value for in execution time.

To achieve these objectives, the implementation was based on a web development paradigm with generally visual components (selects, multi-selects, calendars for date selection), except those values that are necessary to enter into the system for the creation of new high-level features, which inevitably force the introduction of the necessary values.

From a technical point of view, the implementation of the tool was carried out under the Java development language (JDK 1.8), mainly due to the multiple capabilities and features it offers. Since our system is a web application, we relied on its main framework, Spring 5.0, granting an agile development, based on the injection of dependencies and therefore, decoupled and easily scalable. This framework offers by default the Thymeleaf 3.0.4 template engine for the creation of the different views and, in our opinion, perfectly meets the needs imposed, as it allows the definition of reusable fragments and layouts, as well as a wide set of expressions to directly deal with the different data models generated at each step or task performed.

We also used the Bootstrap 4.0.0 framework, which has facilitated the design of the application interfaces, providing the web application with responsive features necessary to adapt the tool to the different existing viewing platforms. Apache Maven 4.0.0 let us manage and build the project in a simple way, as well as define the necessary dependencies of the system, obtaining them directly from its central repository.

Other technologies or frameworks such as jQuery (improvement of the interactivity of the application with the end-user), JUnit 5, Mockito (unit tests of validation of the most important methods of the application and integration of components) and Docker (creation of lightweight containers and highly portable for deployment) were used for the development of the project.

3.2 System working

As already mentioned, the system defines a series of tasks to be performed as an assistant. The system will guide the expert through the following implemented tasks, which are listed and detailed below, in order to be able to design a personalized educational data analysis:

1. Loading of the Moodle log file (Comma Separated Values -CSV- file) of a specific subject, that is, the source dataset to be preprocessed.
2. The expert selects those students not to be included in the final dataset.
3. The system allows the expert to select a date range, discarding all those records that are not inside that period. The system will not allow selecting dates outside the dates range existing in the dataset.
4. The expert selects those resources that he or she does not want to include in his analysis.
5. The system allows the grouping of resources, in order to consider them, from that moment, as the same resource.
6. The system shows for each resource, the different types of actions existing in the dataset, and the expert selects those that he or she wishes to remain in the final dataset (Figure 1 shows a screenshot of this step).

Figure 1. Selection of types of actions

7. The expert establishes the reference date for each resource and type of action (see Figure 2).

Figure 2. Reference dates definition

8. The system selects the first existing action type for each resource and user.
9. The system generates for each student a single record where, for each resource and type of action, it creates an entire attribute. This attribute represents the difference in days, between the reference date and the date recorded in the input file (see Figure 3, where students' names have been anonymized).

User	Sesion1	Read U1	Activity1
Student 1	1	65	47
Student 2	-2	7	14
Student 3	-6	-2	-4
...	3	63	42

Figure 3. Attribute values system generation

10. The system allows the expert to give value to some class attributes for classification purposes (see Figure 4).

User	Final_Mark	Examination_Taken	Numerical_rating	Nominal_rating	Dropout
Student 1	Pass	Yes	8	Notable	No
Student 2	Pass	Yes	9	Sobresaliente	No
Student 3	Fail	Yes	4	Suspense	No
...	Fail	No	0	Suspense	Yes

Figure 4. Class attributes user value definition

11. The expert exports the results obtained to a file with CSV format.

3.3 System output

The system generates a CSV file containing one record per user (anonymized), indicating the degree of advancement or delay in the performance of the activities selected by the expert, according to the date proposed by the tutor, as well as the new features created for classification. Figure 5 shows an example.

```
"User","Teaching Guide viewed","Activity11 viewed","Activity5 viewed","Activity8 viewed",-
"0","-3","1","65","47","3","-1","4","14","1","Pass","Yes","8.0","Remarkable","No"
"1","-2","-2","7","14","-1","11","-5","-2","-3","Pass","Yes","9.0","Outstanding","No"
"2","-3","-6","-2","-4","-2","2","-5","-3","Fail","Yes","4.0","Pass","No"
"3","-27","3","63","42","-1","2","21","8","90","Fail","No","0.0","Fail","Yes"
```

Figure 5. Example of CSV file generated by the system

After conducting some preliminary experiments, it was possible to obtain some interesting minable sights and get some predictive models using Weka¹. Applying, for example, a classification algorithm based on decision trees, we obtain an interesting model to predict whether a student will pass or fail the course. Below, we show the results obtained for this example case:

```
Decision Stump-Classification
Case Study I_viewed <= -2.0 : Pass
Case Study I_viewed > -2.0 : Fail
```

If we look at the predictive model returned by Weka, we find that the activity "Case Study I" becomes especially relevant among all the resources and types of actions of the original dataset. It indicates that all those students who visualize this activity with an advance of two or more days, with respect to the reference date established by the tutor, will finally pass the subject. Otherwise, they will fail.

¹ <https://www.cs.waikato.ac.nz/ml/weka/>

This acquired knowledge could directly influence the decisions that teachers should make regarding the activity, monitoring their development through tutorials with students, reinforcing the teaching material, encouraging students to carry it out or other types of actions.

4. CONCLUSIONS AND FUTURE WORK

In this paper, we have proposed a method that allows generating new features that represent the degree of anticipation or delay of students when completing the tasks suggested by the tutor. Our method is applicable in open courses that adopt methodologies based on the existence of a tutor that guides students by defining a series of continuous tasks that students are encouraged to complete at a certain date.

We have developed a preliminary system that implements that method with Moodle data, and also gives the user the possibility of performing some preprocessing tasks, such as student selection, resource selection, and so on. We have conducted preliminary experiments to obtain some minable sights of different high education open courses. Those tests make us be optimistic about the usefulness of the newly generated attributes and their potential application for future research.

The main future line of research that we should carry out next is the application of the method in different courses and analyze if the new proposed features are valid to predict important educational phenomena such as students' dropout, students' final marks, and so on.

Once a stable release of the system is finished and tested, we intend to provide the community with an access URL so that the system can be publicly used and tested.

ABSTRACT

This research aims to predict the academic performance of students when interacting with an Intelligent Tutoring System (ITS) from emotions detection and analysis. We use data from 47 university students in a virtual learning environment. We have used data gathered from face recording of students' interactions with the system to detect students' emotions and determine to what extent they can predict the final students' performance during the learning session.

Keywords

Predicting performance, Emotion detection, Video analytics.

1. INTRODUCTION

Emotions are a critical component of learning and problem solving, especially when it comes to interacting with computer-based learning environments (CBLEs) [5]. Studies from affective computing literature suggest that facial expressions may be the best single method for accurately identifying emotional states [4]. The automatic detection of emotions techniques are capable of isolating the mood of a learner by means of a facial recognition system through artificial intelligence and there are already tools that enable the processing of data in the form of video, such as the Microsoft Emotion API [1], FaceReader™, etc. However, we have not noticed previous studies testing to what extent the emotion recognition result of these tools is powerful enough to predict student's performance. It could be potentially contributing to enhance the quality and efficacy of CBLEs (e-learning, multi-agent systems, intelligent tutoring systems, serious games, etc.) by including the learner's emotional states.

This research aims to test if student's emotions recognized by and API during a learning session with an ITS can be enough to predict the final student's performance.

2. EXPERIMENTS

Data were collected from 47 undergraduates enrolled at a public university in the north of Spain whom learned about a complex science topic while interacting with the ITS MetaTutorES [3] a

multi-agent computerized learning environment. Participants represented a variety of disciplines, including psychology, education and engineering. The emotion data collected was naturally occurring, the emotions arose from interactions with a the ITS MetaTutorES, designed to teach learners about the human circulatory system during a session ranging from 2:30 to 3:00 hours. During and at the end of the session, performance test about the circulatory system knowledge were taken for every subject, giving a final performance value ranging between 0 and 10, showing 10 the best performance. A pretest about previous circulatory system knowledge is taken at the beginning of the session and final performance is corrected based on that previous level. Videos from every learner's facial expressions were captured with a webcam and analyzed using automatic facial recognition software (Microsoft Emotion API [1]). The API classifies the facial expression in eight classes of emotion: anger, contempt, disgust, fear, happiness, neutral, sadness, and surprise. The analysis allows us to obtain at least one highest emotion during the learning session from every students' frame having a high volume of frames (1 frame for second) for each student in every session. The confidence (values between 0 and 1) gives the likelihood for each class of emotion.

The first step of the experiment consists on check the correlations between the emotions detected and the students' performance. The Pearson correlation test examines the relationship of each emotion with the student's performance obtained during the learning session. The R value in Pearson's correlation coefficient goes from -1 to 1, meaning both values a high level of correlation and 0 a null level of correlation between variables (See Table 1).

Table 1: Pearson correlation test results

Emotion	R-Value
Anger	0.1295
Contempt	0.2165
Disgust	0.0882
Fear	-0.2415
Happiness	0.0459
Neutral	0.0463
Sadness	0.1546
Surprise	-0.1062

According to the results of table 1 none of the variables is highly correlated with the performance. However, based on the axes of emotions valence -positive emotions (happiness); negative emotions (anger, contempt, fear, disgust); non valence (neutral and surprise) [6] and looking at the positive or negative relationship, we can observe that only negative or non valence emotions are negatively related with performance.

Wilson Gustavo Chango Sailema, Miguel Sánchez, Rebeca Cerezo and Cristóbal Romero "Predicting students' performance using emotion detection from face-recording video when interacting with an ITS" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 578 - 580

In the second step, we applied several classification algorithms using the 8 emotions as input attributes for predicting the student's final performance. We used white box classification models (decision trees and rule induction algorithms) because the models they produce (tree and IF-THEN rules) are easy to understand [7]. In our experiments, we selected six well-known classification algorithms provided by WEKA [8]: three decision tree algorithms and three rule induction algorithms (see Table 3).

Table 3: Decision Trees classification algorithms.

Type	Algorithms	Description
Trees	J48	Java implementation of C4.5.
	Reptree	Fast tree learner that uses reduced-error pruning.
	Randomtree	Construct a tree that considers a given number of random features at each node.
Rules	Jrip	RIPPER algorithm for fast, effective rule induction.
	Nnge	Nearest-neighbor method of generating rules using generalized exemplars.
	Part	Obtain rules from partial decision trees built using J4.8

We executed each algorithm using stratified 10-fold cross-validation in which the dataset is randomly divided into 10 disjointed subsets of equal size in a stratified manner. We have compared the test results using the Accuracy and ROC Area evaluation measures (see Table 4).

Table 4. Results produced by all algorithms.

Algorithm	% Accuracy	ROC Area
Jrip	63,8298	0,5820
Nnge	53,1915	0,5290
Part	63,8298	0,6590
J48	63,8298	0,6770
Reptree	48,9362	0,5170
Randomtree	59,5745	0,5950
Avg	58,8653	Error de sintaxis, 0,5932

Table 4 shows that the best results (highest values) were produced by J48 (63,8298%Acc and 0.6770 AUC). Next, we show in Table 5 the obtained decision model by J48 algorithm.

Table 5. J48 decision tree.

Contempt <= 0.126904: Pass
Contempt > 0.126904
Disgust > 0.137741
Sadness <= 0.1977232
Fear <= 0.1551857: Pass
Fear > 0.1551857: Fail
Sadness > 0.1977232: Fail
Disgust <= 0.137741: Pass
Number of Leaves : 5
Size of the tree : 9

The Table 5 show us a decision tree that let us learn some interesting information from. On one side, students who Pass show lower values than an umbral of emotions contempt, disgust, fear and disgust, and students who Fail show higher values than a umbral of these emotions.. On the other side, we can observe that negative emotions have more prediction power on performance than positive or non-valence emotions. And finally, negative emotions values over 0.15 (15% of the session time) are defintory to a Fail ending.

3. CONCLUSIONS

There was an assumption that emotions experienced during complex learning will impact learning and problem solving [2], and therefore, achievement. However, in this study, we observe that student's emotions when interacting with an ITS are not enough for predicting students' final performance. The results give us some information the relationship of each emotion with the student's performance. However could be necessary to refine and redefine the API emotions classification based on an educational psychology framework for some close emotions (e.g attention, engagement, hope, pride, etc.).

Finally, we purpose as a future prospect adding other different variables/attributes from the interaction with the ITS such as log files, eye tracking, etc. in order to obtain higher accuracy values to predict students' performance. We also want to use more classifiers algorithms, particularly deep learning which would perform significantly better than classic methods.

ABSTRACT

This paper presents several strategies that can improve neural network-based predictive methods for MOOC student course trajectory modeling, applying multiple ideas previously applied to tackle NLP (Natural Language Processing) tasks. In particular, this paper investigates LSTM networks enhanced with two forms of regularization, along with the more recently introduced Transformer architecture.

Keywords

next-step prediction, predictive modeling, course trajectory, mooc, lstm, transformer

1. INTRODUCTION AND MODEL OUTLINES

1.1 Fundamentals of Predictive Modeling

Recent innovations in deep learning methods for NLP (Natural Language Processing) tasks such as [7] in the past few years have consistently pushed the state of the art in a wide range of benchmark NLP tasks, while yielding new strategies that can be applied to predictive modeling tasks in a more general sense. This is because the majority of these NLP tasks within the scope of these innovations can be parameterized in terms of modeling the function f in the equation

$$P(y|x_0, \dots, x_t) = f(x_0, \dots, x_t; \theta) \quad (1)$$

where f is a probability mass function with parameters θ over the random variable y , and x_0, \dots, x_t , drawn from a discrete set of tokens T , represent the context from previous time steps. Unfortunately, there is little literature in the domain of education analytics exploring the effectiveness of innovations from NLP for education analytics tasks that also conform to this predictive modeling paradigm. Nevertheless, the LSTM (Long-Short-Term Memory) DNN (Deep Neural Network) architecture, an earlier innovation which was the architecture of choice for predictive modeling tasks in NLP before the past few years, has been successfully applied to several education analytics tasks. These papers demonstrate potential for further exploitation of the similarities between

predictive modeling tasks in education analytics and NLP, while providing a baseline to compare with more recent innovations presented in this paper.

1.2 Previous Work with MOOC Course Trajectory Modeling

One of the first papers to present an application of DNN models for predictive modeling tasks in education analytics is [4], where the authors specifically investigate the applicability of DNN models for modeling student course trajectories in MOOCs (Massive Open Online Courses). Specifically, the authors of [4] demonstrate the effectiveness of LSTM DNN models for this task over other strategies, such as using n -gram models that condition their predictions over small number of past course nodes. Finally, the authors provides suggestion for incorporating such a predictive model in a wider context, including tie-ins with the MOOC service to provide user-facing suggestions and live feedback to monitor the predictive model's performance.

1.3 Baseline LSTM

This model is identical to the Baseline LSTM model featured in [4], using the same LSTM architecture and a nearly identical hyperparameter set and training scheme, further detailed in Section 2.2. This model is intended as a control baseline to assess the performance of other models tested in this paper.

1.4 Transformer Architecture

As noted in Section 1, the shared abstraction of both course trajectory modeling and many NLP tasks as a discrete next-step predictive task suggests applying innovations from NLP to improve performance in course trajectory modeling. In particular, the Transformer architecture, first featured in [7], is one such major architectural innovation.

Transformer Architecture Details. In [7], the authors construct a DNN model architecture centered around modular Transformer blocks as described in Section 1.4. In contrast with the need for $O(n)$ forward and backward passes per input sequence through each of the LSTM recurrent nodes, the entire Transformer model is designed to only require one forward and backward pass through the entire model to process each input sequence. In addition to forming next-step predictive models from these transformer blocks, The authors also provide additional architectural topologies for

Clarence Chen and Zachary Pardos "Applying Recent Innovations from NLP to MOOC Student Course Trajectory Modeling" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 581 - 585

models tailored to other tasks such as machine translation or text classification, emphasizing the applicability of the Transformer blocks for a diverse array of NLP tasks. Please refer to [7] for more information about the composition of a Transformer-based next step predictive model.

Multi-Head Dot-Product Self-Attention. The multi-head dot product self-attention mechanism is the core architectural innovation which enables a Transformer block to fit to temporal correlations present in the training set in one forward and backward pass. On an abstract level, the operation used by the dot product self-attention mechanism with h heads to compute temporal correlations is the the scaled and masked outer product of each $k_i, q_i : i \in \{1, \dots, h\}$ (derived from the input tensor $x \in \mathbb{R}^n \times \mathbb{R}^d$) as shown in Equation (2):

$$t_i = \text{softmax} \left(\frac{\text{mask}(k_i q_i^\top)}{\sqrt{[d/h]}} \right) \quad (2)$$

The results $t_i \in \mathbb{R}^n \times \mathbb{R}^n : i \in \{1, \dots, h\}$ then directly capture how the features of each k_i and q_i are correlated over each pair of time steps in the input sequence. Note that the operator $\text{mask}(\cdot)$ in Equation (2) zeros out lower triangular entries in $k_i q_i^\top \in \mathbb{R}^n \times \mathbb{R}^n$, corresponding to the dot product of features in q_i with features in k_i from previous time steps. Please refer to [7] for more information about the multi-head dot product self-attention mechanism and the the Transformer block as a whole.

1.5 LSTM Enhancements

This section features two different enhancements featured in Kirill Mavreshko's¹ implementation of a Transformer-based next-step predictive model that could be independently used with LSTM models to yield performance improvements for student course trajectory modeling in MOOCs. These enhancements have also been independently backed with theoretical justification and empirical experiments, demonstrating performance improvements in coordinated NLP tasks when applied to LSTM models, as further detailed in [2] and [5].

Confidence Penalty Term in Loss. The baseline LSTM model already features some form of regularization, particularly dropout in the weights of the recurrent layers during training. However, for any classification task with a correct output label y_{true} in a set of possible labels T , examining the equation for the cross-entropy classification loss

$$L(\theta) = -\log P(y_{true}; \theta) = -\log p_{true} \quad p_j = P(y_j; \theta) \quad \forall j \in T \quad (3)$$

suggests an additional regularization term that penalizes highly confident distributions to reduce overfitting. The confidence penalty uses $H(p(y; \theta))$ as quantitative measure of confidence in a model's output distribution, where a higher value represents a lower level of confidence that the model predicts for each outcome $j \in T$. As a result, the new loss

¹Copyright 2018 by Kirill Mavreshko. Source code at <https://github.com/kpot/keras-transformer>

function expands to

$$L^*(\theta) = -\log p_{true} - \beta H(p(y; \theta)) = -\log p_{true} + \beta \sum_{j \in T} p_j \log p_j \quad (4)$$

where β is a scalar hyperparameter weight for the Confidence Penalty loss term. For theoretical arguments and empirical evidence for adding a confidence penalty term, please refer to [5].

Tied Embedding Layers. Another opportunity to introduce additional regularization to any sort of discrete next-step predictive model is found when examining the model's embedding and output layers, specifically

- The embedding layer L with dimension $|T| \times d_{embed}$, mapping input tokens in T to vectors in a latent feature space.
- The output layer W with dimension $d_{final} \times |T|$, mapping the final intermediate layer output h to an probability logit over the set of all input tokens T .

After enforcing the condition $d_{embed} = d_{final}$ by inserting a feed-forward layer between the rest of the model and the output later, W is tied to the embedding layer L fixing $W = L^\top$. For theoretical arguments and empirical evidence for the effectiveness of tying the output layer in this fashion, please refer to [2].

2. EXPERIMENTS AND EMPIRICAL RESULTS

2.1 Dataset Cleaning and Processing

2.1.1 Procedures for Dataset Cleaning and Processing

Given that the task of student course trajectory modeling requires predicting where a student will navigate next given the student's previous navigation patterns, extensive processing of raw MOOC server logs is required before any training can occur. This process is explained in great detail in [4], with the main steps listed below:

1. Given the raw server log records, select the `basic_action` column, timestamp, username, and title columns necessary to build unique course node tokens in step 3.
2. Filter out all log records except those with `basic_action` label `seq_next`, `seq_prev`, or `seq_goto`, representing the full set of navigation actions a student can take for each of the MOOCs.
3. Construct a unique positive integer token ID for each course node through concatenating each component of the full course path to construct a unique name for each course node, then assigning each unique name to the token ID.
4. Assemble the full sequence of navigation records for each user by grouping by user ID, then ordering within in each group by timestamp.

Table 1: MOOC Course Trajectory Dataset Summary Statistics

Institution	Course	Term	Nodes	Users
DelftX	AE1110X	Fa. 2015	291	14496
UCBX	EE40LX	Fa. 2015	287	30633
UCBX	Fin101X	Sp. 2016	114	2951
UCBX	ColWri2.2X	Sp. 2016	54	40698
UCBX	CS169.2X	Sp. 2016	204	940
UCBX	Policy01X	Sp. 2016	129	1804

Table 2: Main Hyperparameters by Architecture Type

Architecture Type	LSTM	Transformer
Max. Seq. Length	256	256
Main Layer Width	128	128
Layer/Block Count	2	2
Attention Heads	N/A	8
Optimizer	Adam	Adam
Learning Rate	0.01	0.0005
Batch Size	128	64

- Prepend the token ID representing the course homepage to every sequence that does not already begin with this token ID, then pad or truncate of the resulting sequences to the maximum sequence length, adding 0 tokens if necessary.

2.1.2 Additional Notes on Dataset Selection

In [4], additional criteria are included for selecting courses used to demonstrate the utility of a student course trajectory model, including approximating of the entropy of each dataset as a set of discrete random processes via fitting a HMM (Hidden Markov Model) to each dataset. For the experiments in this paper, limited access to MOOC trajectory records preempts the utility of filtering out datasets with low entropy over all course sequences. Table 1 provides summary statistics for the six courses chosen for this paper, hailing from the MOOC offerings of these two universities:

- DelftX from the Delft University of Technology in Delft, Netherlands
- UCBX from the University of California, Berkeley in Berkeley, California

2.2 Hyperparameters and Training Context

All training and evaluation was completed on a remote Linux server CPU equipped with 2 GeForce Titan X GPUs (Graphics Processing Units). The script for training and evaluation is written in Python 3 using the Keras [1] deep learning API over a Tensorflow backend. Table 2 provides the full set of hyperparameters used for training and evaluating each model on each course record dataset. As the goal of this paper is to demonstrate specific differences in model architecture and training that lead to performance gains relative to the earlier results, hyperparameter tuning was not done for any of the LSTM models to facilitate comparison with results in [3]. Additionally, minimal hyperparameter tuning was done on for the Transformer models in order to minimize the risk of overfitting to the datasets for each course.

Simultaneous Fitting to Multiple Datasets. Since records from each of the 6 courses were processed as described in Section 2.1 independently, attempting to fit models on multiple courses would result in collisions between different sets of course node tokens. Nonetheless, building a predictive model that can fit to datasets from a wide range of courses is a well-defined area for future research.

2.3 Empirical Results

Table 3 presents summary statistics for each model’s final test accuracy and total training time per batch for each of the six datasets listed in Table 1. Table 4 presents additional metrics for the Transformer model pertinent to the analysis in Section 2.4.3. All statistics in both Table 3 and Table 4 are recorded using the default set of Keras command line logging tools.²

2.4 Analysis and Further Considerations

2.4.1 Baseline LSTM Comparison with Previous Results

At face value, the results for the Baseline LSTM model corroborate those presented in [4], with the caveat that average accuracy metrics reported in [4] are calculated in a different fashion that effectively gives more weight to correctly predicting tokens that occur in shorter course trajectory sequences.

2.4.2 Comparison of Final Test Accuracy Between Models

Table 3 and Table 4 show that the Transformer model achieves an average final test accuracy of around 63 percent, approximately on par with the average final test accuracy of both LSTM models without tied embeddings, in contrast with a marginally yet consistently higher 64 percent average for the LSTM models that use Tied Embeddings (as described in Section 1.5). On the other hand, including the Confidence Penalty (as described in Section 1.5) does not provide any meaningful improvement in final test accuracy for any of the six datasets. As the training scheme for all models featured in this paper invoke early stopping after 3 epochs without improving validation loss, training any of the above models for more epochs will most likely lead to overfitting on the training set.

2.4.3 Further Analysis of Final Test Accuracy for Transformer Models

At a first glance, the final test accuracy results in Table 4 seem to contradict Transformer models’ considerable performance improvements over LSTM models demonstrated in [7]. Nevertheless, the largest dataset featured in this paper only includes 40,698 course trajectory sequences, which is multiple orders of magnitude smaller than the WMT machine translation datasets used in [7] with millions of sentence pairs per language pair. This discrepancy in dataset size can cause overfitting for a particular deep learning architecture optimized to train with much larger datasets, even while controlling for model and training hyperparameters. Furthermore, the final training accuracies listed in Table 4 suggest that the Transformer model has overfit to

²BaseLogger and ProbarLogger Callback utilities. [1]

Table 3: Overall Performance Metrics by Architecture

Model	Baseline LSTM	LSTM w/ Conf. Penalty	LSTM w/ Tied Emb.	LSTM w/ Both Enh.	Transformer
Final Test Accuracy					
Average	0.6373	0.6355	0.6418	0.6388	0.6383
Std. Dev.	0.05623	0.05558	0.05728	0.05592	0.05455
Training Time per Batch					
Average	35 ms	35 ms	35 ms	35 ms	2 ms
Std Dev.	0.94 ms	0.92 ms	0.89 ms	0.86 ms	0.04 ms

Table 4: Additional Performance Metrics for the Transformer Model

	Test Acc.	Train Acc.
Average	0.6307	0.6383
Standard Deviation	0.06081	0.05455
Avg. for Large Datasets	0.6438	0.6411
Avg. for Small Datasets	0.6175	0.6355

the smaller datasets in this paper despite the use of early stopping, particularly for the following two datasets from courses with fewer than 2,000 unique users as recorded in Table 1:

- UCBX CS169.2X with 904 unique users
- UCBX Policy01X with 1,804 unique users

In conclusion, these results provide evidence that Transformer-based models do not yield benefits in accuracy over LSTM models when trained with datasets of similar size to the MOOC course trajectory datasets featured in this paper, in contrast with the much larger datasets common to certain NLP tasks such as machine translation.

2.4.4 Further Analysis of LSTM Enhancements

Given that both the Tied Embedding Layers and the Confidence Penalty are theoretically motivated by a search for new forms of model regularization, the empirical results in Table 3 indicate the Tied Embeddings are a marginally more effective form of regularization than the Confidence Penalty for this task. Furthermore, since the Tied Embedding enhancement specifically targets the input embedding and output layers of a discrete next-step predictive model for regularization in contrast to the Confidence Penalty altering the entire model’s loss function, the embedding and output layers of each of the LSTM models play a disproportionately important role in the model’s performance as a whole for this task.

2.4.5 Analysis of Training Time Results

In contrast to the Transformer model’s lack of improvement in final test accuracies for all six datasets, the results in Table 3 and Table 4 suggest that the Transformer model outperforms all types of LSTM models by more than an order of magnitude with respect to total training time per batch. Given that both the LSTM and Transformer models are built to accommodate a maximum sequence length of 256 as indicated in Table 2, the results in Table 4 are consistent with the reduced number of training passes through the

model’s computational graph per input sequence, as encapsulated in the Transformer architecture’s design goals from Section 1.4.

2.5 Directions for Future Research

2.5.1 Task-Specific Model Enhancements

As mentioned in multiple sections of this paper, certain task-specific strategies for improving performance on MOOC course trajectory prediction covered in [4] are not investigated in this paper, even if applying these strategies in conjunction impact performance in a noteworthy manner. Some of these additional strategies used to improve performance on these two tasks include:

- Calculating the entropy of each dataset’s best-fit HMM transition matrix as a criterion for selecting MOOC course trajectory datasets used to evaluate the enhanced LSTM and Transformer models.
- Incorporating auxiliary data inputs, including the time difference between course navigation actions, into evaluating the benefits of enhanced LSTM models and Transformer models over baseline results from [4].

2.5.2 Model Pre-Training and Multitask Learning

Another more ambitious goal for further research involves constructing one model that can provide meaningful predictions for multiple tasks with minimal training needs. Given the wide applicability of models with generalized predictive modeling capabilities, this model would most likely incorporate innovations originally designed to provide multitask capabilities for NLP applications. For example, [6] presents a NLP model that is first trained to perform a next-word prediction task on large text datasets before undergoing fine-tune training for more specific downstream NLP tasks, which include tasks such as text classification, sentence embedding, question answering and free-form text generation. In the context of education analytics tasks, an analogous suite of tasks for such a model could include modeling overall course performance and individualized suggestions for instructors assisting students with course material.

Return of the Student: Predicting Re-Engagement in Mobile Learning

Maximillian Chen
Cornell University
mlc294@cornell.edu

René F. Kizilcec
Cornell University
kizilcec@cornell.edu

ABSTRACT

Mobile learning platforms cater to intermittent microlearning by lowering the barrier for re-engaging in the learning process after a period of disengagement. We examine student re-engagement in the context of an SMS-based mobile learning platform, how to predict it and how it differs from disengagement. In a sample of 87,651 Kenyan students, we analyze data on 1,196,780 quiz attempts, finding that 36.3% of students who disengage for a week or more eventually re-engage on the platform. They spend more time on quizzes early on than students who stay disengaged. A Random Forest classifier trained on two days of student activity logs predicts disengagement and re-engagement with similar performance: F1 scores of 81.2% and 80.9%, respectively. The prevalence of re-engagement in mobile learning calls for more research into this behavioral outcome.

1. INTRODUCTION

As the world becomes increasingly connected through mobile technology, mobile devices are becoming an increasingly viable medium for education. Not only are mobile phones more affordable than traditional personal computers, but mobile devices have shallower learning curves, as they require lower levels of literacy and training [14]. The accessibility of mobile technology is especially advantageous in resource-constrained areas. It provides students access to educational resources without having to make substantial economic trade-offs associated with desktop computers. Given the rapid development of mobile computing power, many people in developing economies are predicted to skip purchasing desktop computers altogether and instead adopt mobile devices [6]. In comparison to traditional online learning platforms, mobile learning platforms remain relatively understudied despite their promise for accessibility.

A common concern with self-directed learning tools is that students do not stay engaged on the learning platform for long. The issue of disengagement, defined as a drop in student activity on the platform, has been studied extensively,

for instance in the context of Massive Open Online Courses (e.g. [16, 15, 12, 8]). However, it remains largely unstudied in the context of mobile learning environments. Student engagement patterns likely vary between desktop and mobile learning environments, considering how many different applications are available [2] and how deeply embedded mobile devices are in people's everyday lives. In fact, mobile learning platforms have been found to provide unique opportunities for microlearning sessions, where learning tasks are broken into shorter chunks that can be managed "on-the-go" [4]. Especially considering the low barriers to entry and exit in most mobile learning applications, it is unsurprising that a sizable proportion of students engage and disengage freely, which can result in longer gaps of inactivity. These intermittent usage patterns require that we consider re-engagement as a distinct behavior in mobile learning and how it compares to disengagement. Insights from this work can advance our understanding of how mobile learning works in practice and how platforms may support at-risk students through intervention.

In this research, we propose definitions of disengagement and re-engagement in mobile learning, analyze differences in behavior between disengaging and re-engaging students, and apply supervised machine learning approaches to predicting disengagement and re-engagement in mobile learning. We find that 36.36% of students who disengage for a week eventually re-engage on the platform within two weeks. A Random Forest classifier trained on two days of student log data can predict re-engagement after two weeks with an F1 score of 80.9%, showing that early platform activity is indicative of which students will return later on.

2. BACKGROUND

2.1 Beyond Student Disengagement

Before defining re-engagement, we need to formally define its prerequisite: disengagement. Defining disengagement in mobile learning platforms presents a challenge, because many such platforms are inherently less rigid and prescriptive in their learning design compared to online learning environments such as massive open online courses (MOOCs). MOOCs tend to lay out a clear path through course materials with deadlines, while many mobile learning platforms provide more room for self-directed learning and agency in choosing a learning path. This calls for an updated definition of disengagement for the context of mobile learning.

Disengagement is defined conceptually as a "lack of engage-

Maximillian Chen and Rene Kizilcec "Return of the Student: Predicting Re-Engagement in Mobile Learning" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 586 - 590

Figure 1: Three students’ daily activity for 60 days after signing up: student 1 disengages; student 2 stays engaged; student 3 disengages and re-engages.

ment,” and has been operationalized in terms of students’ interaction with or completion of learning objectives, depending on the structure of the learning platform [12]. In past studies in the context of MOOCs, disengagement has been defined as a “lack of interaction” [9, 1], the point in time where a student “fails to submit any further assignments” [15], failure to earn a course certificate [5], failure to complete a set of modules [3] or a lack of platform interaction combined with a lack of progress towards course completion [12]. Despite the many studies defining and predicting engagement in MOOCs, research on modeling engagement in mobile learning is scarce [7] and definitions of disengagement may not translate well from MOOCs to mobile learning. Definitions focusing on course completion do not apply in a context that is unlike a course, and definitions focusing on an absence of platform interaction may incorrectly label students who disengage early but return to the platform later on. Mobile learning platforms offer more opportunities for “microlearning” sessions in which students are able to learn in short bursts sporadically or “on-the-go” [4].

A recent study on engagement patterns in mobile learning on the same platform as in this research found students tend to be engaged in learning activities during the first few days after signing up but disengage shortly thereafter. In fact, 75% of all students disengaged within two days of registering, and even among the cluster of engaged students, 68% of them appeared to disengage in the first ten days [7]. However, whether a student has completely disengaged can be unclear at first sight. Consider the three actual students whose activity over time is visualized in Figure 1. All three are engaged in the first week, but student 1 disengages and never re-engages, while student 2 is inactive during the second week but occasionally returns to complete quizzes over the next two months. Student 3 was engaged on the day of registration but then disengaged for 60 days before re-engaging. We therefore define a re-engaging student as one who disengages but then returns to the mobile learning platform. This more accurately characterizes student behavior in the long run and with some additional granularity.

The ability to distinguish re-engaging students from disen-

gaging students has practical applications, such as for an automated student support system. The system could send different kinds of text messages or notifications to students who are classified as disengaging (i.e. not ever re-engaging) based on their activity in the first few days. By targeting students based on their predicted behavior, providers can tailor reminders to groups of students to highlight learning opportunities without alienating students who are already likely to re-engage in the absence of nudging.

2.2 Predicting Student Engagement

As there have not been any large-scale studies predicting student engagement in mobile learning to date, we build on a large literature on predicting student engagement and intervention systems in the context of MOOCs [16, 12, 15]. As is the case in MOOCs, a vast majority of students on mobile learning platforms eventually disengage. Any supervised learning approach in which labels correspond to engagement/disengagement would therefore suffer from class imbalance, i.e., the distribution of class labels is heavily skewed [10]. A naive classifier could simply predict the majority label for all instances and achieve a high degree of accuracy without successfully identifying actual engagement. Nagrecha and colleagues [12] addressed this issue by re-sampling their training data to balance the distribution of their labels, as was done in prior work predicting student disengagement [11]. Due to class imbalance, model accuracy can be a misleading evaluation metric, and prediction recall is frequently used as a substitute. Likewise, in this study, we face a heavy imbalance in class labels (very few students re-engage). We therefore opt to re-sample our data during training and evaluate our models using both recall and F1 score.

The user interface of mobile learning platforms tends to be simpler than ones designed for larger computer screens. For example, MOOCs tend to have more advanced platform features than mobile learning applications, such as video playback options and non-traditional assessment types. Prior studies have focused on engineering features relevant to interaction with video lectures, such as “number of straight-through video plays” or “number of video views per session” [9]. But clickstream data (interaction logs) are more informative about interactions with the structure of a platform than any specific course, which is why they were found to offer strong predictive power when analyzing data across multiple courses on a learning platform [17]. We pose two research questions in this study:

RQ1. How does the behavior of re-engaging students compare with those who stay disengaged?

RQ2. What features are predictive of student re-engagement?

3. METHODS

3.1 Platform Background & Dataset

We study re-engagement on a text message-based mobile learning platform called Shupavu 291. It has been used by over 5 million students and it offers content for over 800 distinct curricula. The platform was developed by Eneza Education¹ to provide a learning resource in regions with

¹<https://enezaeducation.com/>

Table 1: Daily student activity features for two days.

Feature Name	Definition

n_unique_quizzes.i	Num. of unique quizzes completed on day i
nsummary.i	Num. of quiz results viewed on day i
nhw_tools.i	Num. homework tools (e.g. dictionary) used on day i

limited access to education. Shupavu 291’s user base primarily consists of Kenyan students, though its influence is growing in other African countries. The platform was designed by a group of Kenyan teachers, and the course materials align with the topics and learning outcomes of the Kenyan national curriculum for numerous subjects in primary and secondary education. Every interaction with Shupavu 291 is via text message. Students navigate through menus and quizzes by sending a text message containing a number corresponding to a menu item from the options relayed to them. Students are able to choose from a variety of grade-specific subjects such as “Fractions” and “Kiswahili.” For a given subject, students choose a specific topic and receive compact lecture notes followed by a quiz (generally five multiple-choice questions). Quiz questions follow the menu format and are sent individually; students receive instant feedback on correctness along with an explanation. Students may retake quizzes as many times as they like or use the “Ask-A-Teacher” feature to ask teachers for help.

Shupavu 291 stores a record for every quiz or platform interaction a student completes. The dataset used consists of 21,302,582 platform actions, including 1,196,780 quiz attempts, from 87,651 students in Kenya. Data beyond self-reported grade level and platform interactions for each student is completely de-identified. For the purpose of this research, we construct two sub-samples, where each one is used to solve a separate prediction problem. The first sample consists of the 87,651 students who completed at least one quiz on Shupavu 291 (an indicator of their willingness to engage with content). The second sample consists of those 63,120 students in the first sample who exhibited a seven-day period of inactivity (i.e. disengagement). The sample definitions are explained further in the next section.

3.2 Defining the Prediction Task & Features

We define two separate prediction tasks: predicting disengagement, and predicting eventual re-engagement. A disengaging student is defined as one who is inactive (here, not attempting quizzes) for at least seven consecutive days. A re-engaging student is defined as one who has disengaged and then is active (here, attempts quizzes) for at least two different days within the 14-day period following the period of inactivity. As in most disengagement prediction problems [12], we found a significant imbalance in observed labels for both disengagement and re-engagement: 72.01% of students were labeled as disengaging, and 63.68% of them were labeled as remaining disengaged (i.e. not re-engaging). We thus trained our classifiers on data that was randomly re-sampled to achieve a more balanced label distribution.

Figure 2: Distribution of the number of interactions with different parts of the platform in the first two days for students who re-engage and those who stay disengaged.

Due to the rapid decline in student engagement after registration, we devise features to capture activity on each student’s first two days on the platform. We expect early engagement to be predictive of disengagement and re-engagement. The features, defined in Table 1, capture how students interact with key components of the Shupavu 291 application and generalize across multiple subject areas, similar to the method used by Taylor and colleagues [15]. Min-max normalization is performed for each feature for each student’s first two days. We fit a Random Forest (RF) to predict whether students disengage, then another RF to predict their re-engagement. Model performance is evaluated using Recall (as suggested in [12]) and F1 scores (the harmonic mean of Precision and Recall), where a “true positive” is a student who disengages (or remains disengaged). We optimize model hyper-parameters to maximize F1 scores through exhaustive 5-fold cross-validated grid search using scikit-learn [13].

4. FINDINGS

We find that more than a third (36%) of students who disengage (seven days of inactivity) eventually re-engage on the Shupavu 291 mobile learning platform. The prevalence of re-engagement in this learning context speaks to the importance of considering this engagement pattern in mobile learning more broadly. To address the first RQ about differences between disengaging and re-engaging students, we compare student activity in the first two days after registering on the platform. Actions on Shupavu 291 are grouped into six categories:

- *Registration*: managing Shupavu 291 subscriptions.
- *Menu*: navigating the menu structure.
- *Lessons*: using course material, e.g. completing lessons.
- *Quizzes*: answering quiz questions, checking quiz grades, or starting quizzes.
- *Platform Features*: using Shupavu 291-specific resources,

e.g. the dictionary or ask-a-teacher feature.

- *Miscellaneous*: any other interaction, e.g. promotional events and features.

Overall, disengaging and re-engaging students behave similarly, spending most of their time interacting with quizzes (Figure 2). However, re-engaging students interact significantly more with quizzes (56.00% v. 47.57%, $\chi^2 = 25083, p < 0.001$) and slightly more with lessons (11.45% v. 10.34%, $\chi^2 = 1109.6, p < 0.001$, while disengaging students have more registration events (13.30% v. 7.25%, $\chi^2 = 35827, p < 0.001$). Having a greater proportion of registration events may be an indication that students who stay disengaged were already spending less time engaging with Shupavu 291 even within their first two days. A greater proportion of academic (quiz and lesson) events is likely an indication that students who eventually re-engage were more active students early on. The finding that re-engaging students engage with more academic events early on is notable, as quizzes and lessons are the core functions of Shupavu 291.

4.1 Predicting Modes of Engagement

We fit an RF² to predict disengagement and re-engagement using a set of features that capture early platform activity (Table 1). The model achieved good results for the disengagement prediction task, with a testing F1 score of 81.21% and Recall of 83.06%. Fitting the same RF to predict re-engagement received comparable performance: 80.91% F1 score and 84.19% Recall. This suggests that it is possible to train a useful classifier for both behaviors using early engagement features.

To better understand which kinds of early behaviors predict each outcome, we compare variable importance scores between the models in Figure 3. The number of quizzes completed on both day 0 and day 1, time spent on day 1, and number of platform features (questions asked, homework tools, quiz summaries) used on both day 0 and day 1 are more important for predicting re-engagement, whereas the other features are more important for predicting disengagement. This suggests that quiz engagement and diversity of platform usage is especially predictive of a student's likelihood to re-engage, though many of these characteristics are also predictive of disengagement. The importance of time spent on day 1 for predicting re-engagement is notable because it indicates that long-term behavior is related to sustained activity. Aside from the finding that diversity of platform usage is more important for predicting re-engagement, Figure 3 also suggests that specific platform feature usage (e.g. "Ask A Teacher") is not as indicative of student engagement as in prior work with MOOCs [9]. Overall, we find that early usage behavior is predictive of students' subsequent engagement pattern, which provides a basis for developing automatic interventions to better support students.

5. DISCUSSION

This study shows the prevalence of re-engagement in mobile learning. This behavioral outcome can be defined in many different ways and the optimal choice will depend on the context of the learning environment and broader goals of the

²1,000 trees, 2 samples/split min., 1 sample/leaf min., 25 tree depth limit, Gini criterion, optimized for F1 score

Figure 3: RF Gini Importance by prediction problem. Number of quizzes completed and time spent after the first day are more important predictors of re-engagement than disengagement.

predictive model. In particular, the periods of time and the thresholds of activity to determine dis- and re-engagement can be tweaked to fit context and goals. In the context of Shupavu 291, which has rapid disengagement, most periods of inactivity occur soon after registration. Most predictive models are not also explanatory models and this is no exception. While it is feasible to predict how a student will behave, it is unclear why they (choose to) behave in that way. A student who is active early on but disengages for a seven-day period several weeks after registering could be treated differently than one who disengages early on for the purpose of targeted intervention. Yet more work is needed to discern how to support students differentially in light of their predicted outcome.

One of the limitations of this study lies in how the second prediction problem is set up. The model is trained only on the subset of students who disengage, because by our definition, a student who does not disengage cannot re-engage. Alternatively, we could have taken the output from the disengagement prediction model and predicted the joint likelihood of disengaging and re-engaging. However, this would have introduced a great deal of uncertainty from the disengagement task into the re-engagement task. Another alternative is to set up the re-engagement prediction task as identifying students who disengage and then re-engage; however, in this case, all other students are then a mix of those who disengage completely and those who remain engaged the entire time—two groups which exhibit very different behaviors. Restricting the sample to only disengaged students gives up some information, but provides a clear basis of comparison for predicting disengaging and re-engaging students.

This research contributes an empirical treatment of student re-engagement in mobile learning and one of the first large-scale studies of student interaction with a mobile learning platform, especially in the developmental context of Sub-Saharan Africa, where mobile learning provides students with affordable access to study resources outside of formal schooling. We find it is possible to predict and distinguish between disengaging and re-engaging students using early clickstream data, providing a foundation for more research into patterns of re-engagement.

ABSTRACT

Research has shown that autonomy can be beneficial to both learning and motivation; however, limited research has explored unsolicited hints impacts on students' autonomy. Furthermore, some research has shown that unsolicited hints can improve student learning while other research suggests that on-demand hints are more beneficial. In this study, we compare three types of student autonomy regarding hints: 1) *Control*, with on-demand hints, 2) *Choice*, with periodic popups asking whether the student would like a hint, and 3) *Assertions*, with periodic unsolicited hints. We found that the Control and Assertion groups performed similarly, and significantly better on the post-test than Choice. Further, the Assertions group had the fewest steps where help was needed but was not received, effectively solving the help avoidance problem. Overall, our results suggest that unsolicited hints can effectively ensure that more help is delivered when it is needed, reducing autonomy without reducing learning.

1 Introduction

Although research has shown that allowing students to have autonomy while learning a new domain can benefit learning [6, 18, 19, 17, 7], studies have shown that students many not have the required skills to self-regulate their learning to seek help appropriately [2, 13, 22, 12, 3, 2]. Further, research has shown that students often cannot make effective decisions regarding when they need a hint [22]. Students lacking help-seeking abilities often partake in help avoidance, where they do not use assistance available in a tutoring system [1, 15]. To address help avoidance, some ITSs employ proactive assistance [21]. While one paper found that on-demand assistance, where students have to request hints, produced

Christa Cody, Mehak Maniktala, David Warren, Min Chi and Tiffany Barnes "Does autonomy help Help? The impact of unsolicited hints and choice on help avoidance and learning" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 591 - 595

better learning outcomes [16], other studies have shown that providing tutor-initiated, unsolicited hints at the appropriate time, i.e. with no student autonomy about hints, can augment students' learning experience and improve performance [5, 14, 4].

The goal of this work is to investigate whether unsolicited hints can solve the help avoidance problem. We compare three groups: 1) *Control*, with on-demand hints, 2) *Choice*, where students were periodically asked if they would like a hint, and 3) *Assertions*, where unsolicited hints were periodically added to the student's workspace without any element of student choice. The Assertions group provided students with the least autonomy regarding when to receive a hint, by adding unsolicited hints to the workspace. Students may ignore these hints, but as they are the most efficient next step, students avoiding them will have less efficient solutions. The Choice group is the middle ground for hint autonomy because students can choose not to receive a hint. Due to the need to make a help-seeking decision, we consider this group to have a medium level of hint autonomy. The Control group is considered the most autonomous because they control the entire interaction surrounding hints. Overall, we hypothesize that the benefit of receiving help when it is needed outweighs the negative impact of removing student autonomy about when and whether to receive a hint.

We constructed the following hypotheses based on prior work in Deep Thought, a logic tutor, and research in students' self-regulation abilities: H_1 , Assertions will increase the chances of receiving help when it is needed, while not harming performance; H_2 , the Choice group will demonstrate more help avoidance than the Assertion group and worse performance in the posttest due to bad self-regulation choices; and H_3 , the Control group will also demonstrate more help avoidance than the Assertion group, and take longer in the training, but have similar performance in the posttest.

2 Deep Thought, our logic tutor

Our propositional logic tutor, Deep Thought, [11] presents proof problems as a set of given logic statements, shown at the top of the workspace and a conclusion to be derived at the bottom of the workspace (see Figure 1). Students solve problems by iteratively deriving new logic statement nodes until they derive and justify the conclusion. To create a

new statement node, students first ‘justify’ it by selecting 1-2 existing nodes and a rule to apply to them. The tutor is divided into an introduction, pretest, training, and posttest. The introduction includes two worked examples where students click through the derivation and justification of all the nodes, followed by one practice problem to learn the interface. Next, a student takes the pretest problem, which we use to compare the student’s incoming proficiency for stratified sampling (see Section 3). Next, the tutor guides students through the **training** section (15 problems) with varying difficulty, where students can request and receive hints. Finally, students take a more difficult non-isomorphic **posttest**, where all students must solve the same set of 4 problems without any tutor assistance. Throughout the tutor, including the pre- and post-test problems, our logic proof tutor provides immediate error feedback for rule application mistakes.

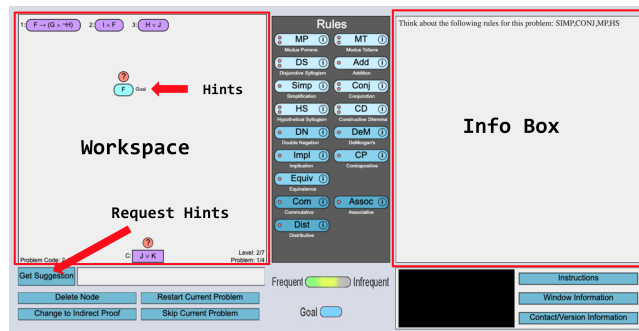

Figure 1: The Deep Thought interface.

2.0.1 Assistance

The tutor uses a data-driven approach based on a modified version of Hint Factory [20, 9] to generate hints from historical student data, resulting in hints on the most *frequent* and *efficient* paths available based on the student’s current attempt. Hints provided in the training of the tutor can either be initiated by the student, in which case they are called *on-demand* hints, or they can be initiated by the tutor, in which case they are called *unsolicited* hints. For our hints, we used our recently-designed Assertions interface [9] to place next-step hints in the workspace, which are the next, best statement that can be derived in one rule-application step from the student’s current state, as blue nodes marked with a question mark (denoting that they have not been justified) and a ‘Goal’ label. Although each group received hints through the Assertions interface for a fair comparison, later iterations of the tutor use the Assertion interface only for unsolicited hints. Hints do not tell students which rules or prior nodes can be used to justify the suggested statement and are designed to help students solve problems by suggesting a subgoal statement to help them break down multi-step problems.

3 Methods

The tutor was used as a mandatory, online homework assignment by students in an undergraduate discrete mathematics for computer scientists course (Spring 2019). For this study, we compared 94 students’ data from three conditions to investigate the impact of student-choice on performance and behavior. The three conditions were 1) **Con-**

trol, 2) **Choice**, and 3) **Assertions**. While all conditions allowed on-demand hints, they differed slightly in unsolicited help. The **Control** group represents the normal conditions in Deep Thought with no unsolicited hints. The **Choice** group was asked “Would you like a suggestion?” after completing approximately every third step to expose poor self-regulating decisions. We chose this amount to be frequent enough to be comparable to the **Assertion** group, but not distracting. The **Assertions** group received periodic unsolicited hints on approximately 40-50% of the steps to produce assistance similar to a partially worked example, or turn-taking tutor where the tutor and the student co-construct a solution to the problem.

We used stratified sampling, splitting students by pretest performance, then randomly assigning them to **Assertions** ($n = 38$), **Choice** ($n = 27$), and **Control** ($n = 29$) to ensure all conditions were balanced in incoming knowledge. The **Assertions** group was designed to have a slightly larger size to ensure sufficient data collection, and since we felt that this condition would be more beneficial to students than the **Choice** or **Control** conditions.

We used each student’s pretest **score** to measure incoming knowledge. A student’s **score** is a combination of normalized metrics for the pretest *time*, number of *steps*, and *accuracy* on a single problem, which ranks a student based on how fast, efficient, and accurate they are compared to their current peers. To investigate student’s performance, we focused on time spent solving a problem, total attempted steps, and accuracy. **Total time** is counted from the moment a problem is on the screen until it is solved by deriving and justifying the conclusion. **Total steps** in a problem include any attempt a student makes at deriving a new step, which includes both correct and incorrect steps (node derivations). **Accuracy** is the total number of correct rule applications divided by all rule application attempts. Note that the tutor is not designed or assumed to promote large improvements in accuracy, since no penalties are assigned for incorrect rule applications, even within the pre- and posttests. We focus on steps and time per problem because it is more difficult for students to learn to determine which steps to derive to achieve shorter, more efficient proofs. Whereas, learning how to apply the rules can be done by memorization and simple practice.

Data were analyzed to compare groups for the pretest, training, and posttest portions of the tutor. ANOVA with Tukey’s post hoc tests were used to examine the significance of differences in the means of the populations between pretest groups with Benjamini-Hochberg corrections. For training and posttest metrics, we applied one way ANCOVA using the pretest as a covariate. To check that the data met assumptions, we used the the Shapiro-Wilk’s W test, Levene’s test, Q-Q plots, and histograms. Data that did not meet the assumptions were transformed using log or square-root transformations, then re-inspected. Data reported in tables are before transformation for clarity. For all tables, at least marginally significant values are bolded ($p \leq 0.10$), and significant values are marked with an asterick (* for $p \leq 0.05$).

4 Results & Discussion

This section discusses the comparison between the **Assertion**, **Choice**, and **Control** groups, and the differences in per-

formance between students.

4.1 Hint Usage and Help Need

To understand each group’s utilization of hints, we examined hint-related metrics. **# Hint Requests** is the total number of hints requested in training. **Hints Received** is the total hints a student received during the tutor, unsolicited and requested. For the Choice group, **# Asked** represents how often they were asked if they would want a hint. **Hint Justification** rate is the percentage of hints received that students connected to their current solution through justification. Table 1 shows the mean, standard deviation and Tukey HSD’s results for the hint metrics. ANOVA showed a significant difference in the mean # Hints Received ($F(2, 91) = 25.576, p < 0.01$) between the groups. Tukey Contrasts analysis showed significant differences among each comparison (Control-Choice ($p < 0.01$); Choice-Assertions ($p < 0.01$); and Control-Assertions ($p < 0.01$)). We expected these differences because the Assertions group was given frequent, unsolicited hints, the Choice group was asked if they wanted a hint at a slightly lower frequency and was only given a hint if they selected ‘Yes’, and the Control group received hints only upon request. Since all three groups could request on-demand hints in addition to any the tutor might provide or offer, we compared # Hints Requests, but there were no significant differences between the 3 groups on this metric ($F(2, 91) = 0.1816, p = 0.83$)).

Table 1: Mean and Standard Deviation(SD) of the Hint Usage Metrics in the Training.

	Control <i>n</i> = 29	Choice <i>n</i> = 27	Assertions <i>n</i> = 38
<i>Metric</i>	<i>Mean(SD)</i>	<i>Mean(SD)</i>	<i>Mean(SD)</i>
# Asked	34(10)	-	-
# Hints Received	19(16)*	35(25)*	51(12)*
# Hint Requests	21(21)	26(27)	25(23)
Hint Justification Rate	85%(25)	80%(20)*	84%(6.5)*

The Control group justified 85% of the requested hints, on average, which makes sense as students are more likely to use the hints they request [16]. The mean Hint Justification rates were 84% for Assertions and 80% for the Choice group. ANOVA results revealed a significant difference between groups for the Hint Justification Rate ($F(2, 91) = 6.0633, p < 0.01$)). Tukey Contrasts analysis showed significant differences among Control-Choice ($p = 0.03$), and Control-Assertions ($p < 0.01$)), but no significant difference between Choice and Assertions group ($p = 0.79$). This is surprising because we expected the Choice group to have a higher Justification rate than the Assertions group, since, similar to the Control, they chose to get a hint. These results suggest that unsolicited Assertions were just as well received as hints offered as a choice.

Further, we defined measures to address all three hypotheses concerning hint usage: help need, hint abuse, unnecessary hints, and steps in which they received an appropriate level of help (i.e. received a hint when needed and did not receive a hint when not needed). An important goal of this study was to investigate whether periodic unsolicited hints could address help avoidance by increasing the number of times students who needed help received it. Since our hints are partially-worked steps and students could easily ignore them, unsolicited hints should not harm students who do

not need them. We determined when a hint was needed vs. not needed via our new Help-Need model described in [8, 10]. The model uses (1) the quality of the current step based on a combined productivity measure of the optimality of their current state (how close it is to the solution based on the Hint Factory [20]), and the time taken to derive it, and (2) a prediction of whether help is needed in the next step (e.g. if the next step is not predicted to be productive, then help is needed). We note that our help-need predictor is not ground truth, but our cited work shows that the Help-Need predictor is correlated with post-test performance. **% Help Needed** is the percentage of total steps our Help-Need model identified as unproductive, where a student could have benefited from a hint, and a hint was not received **% Hint Abuse** is the percent of total steps where our model predicted no Help-Need but a student *requested* a hint, representing a bad help-seeking decision. **% Unnecessary Hint** is the percent of total steps where students *received* a hint on a step where we predicted no Help-Need, including both help abuse requests and the number of times hints were given but not needed. We also included Help Abuse because we wanted to ensure none of the conditions were promoting gaming the system. **% Appropriate Hint** is the percent of steps where Help-Need model aligned with the student need (e.g. a student received a hint when they were predicted to need one or a student did not receive a hint and the model labelled the step as no help-needed).

Table 2 shows the differences in these metrics between the groups. With ANCOVA, controlling for the pretest, we found a significant difference between the groups for % Unnecessary Hints ($F(2, 91) = 38.35, p < 0.01$) and % Help Needed ($F(2, 91) = 10.11, p < 0.01$). For % Unnecessary Hints, Tukey Contrasts analysis revealed significant differences between all 3 groups: Choice-Control ($p = 0.01$), Choice-Assertions ($p < 0.01$), and Control-Assertions ($p < 0.01$). For % Help Needed with the same procedure, we found significant differences between Choice-Assertions ($p = 0.01$) and Control-Assertions ($p < 0.01$); however, there was no significant difference in Control-Choice ($p = 0.45$). There were no significant differences for Hint Abuse ($F(2, 91) = 0.04, p < 0.96$) or the Appropriate Hint metrics ($F(2, 91) = 0.57, p < 0.56$).

Table 2: Mean and Standard Deviation(SD) of the Help Need Metrics in the Training.

	Control <i>n</i> = 29	Choice <i>n</i> = 27	Assertions <i>n</i> = 38
<i>Metric</i>	<i>Mean(SD)</i>	<i>Mean(SD)</i>	<i>Mean(SD)</i>
% Help needed	20(12)	16(11)	10(8)*
% Hint Unnecessary	4(5)*	7(5)*	15(4)*
% Help abuse	7(6)	9(9)	7(7)
% Appropriate Hint	72(11)	71(12)	73(7)

The Control group had the lowest percentage of steps with Unnecessary hints, which was expected since they had full autonomy and requested fewer hints than the other groups. The Control group also had the highest percentage of steps where Help-Need was detected, meaning that these students spent more time in steps being unproductive. The Choice group fell in the middle for both % Help Needed and % Unnecessary Hints. H_2 , stated that the Choice group would have more help avoidance than the other two groups. The Control group showed similar help avoidance to the Choice

group by not requesting hints when needed. However, the Choice group had a significantly higher Help Avoidance than the Assertion group, which provides partial evidence in support of H_2 . Additionally, the Control group having a significantly higher % Help Needed partially supports H_3 , in which we hypothesized that the Control group would not request hints often enough. The Assertions group decreased steps where students needed help but were not receiving it, confirming H_1 . Although more unnecessary hints were provided, our goal was to reduce students being stuck in steps without receiving help, which was achieved even though the frequency of unsolicited hints was not based on an intelligent policy. Incorporating an intelligent policy to determine when to give a hint should result in an even smaller percentage of help need and reduce instances of unnecessary hints. To test whether the larger percentages of Unnecessary Hints would be worse for posttest performance, a simple linear regression was calculated to predict the posttest score based on the % Unnecessary Hints and was not significant ($F(1, 91) = 0.33, p = 0.57$). Therefore, we do not believe these Unnecessary Hints had a significant impact on performance. Another simple linear regression was calculated to predict the posttest score based on the % Help Needed, and a significant regression was found ($F(1, 91) = 8.49, p < 0.01$) providing support that addressing help need is important.

4.2 Evaluating Students' Performance Across the Tutor

To examine the effects on performance each group had, the pretest and posttest performance metrics for the 3 groups were analyzed (see Table 3). ANOVA was performed on pretest metrics to determine if there was a similar distribution of proficiency between the groups. There were no significant differences between the groups on Total Time ($F(2, 91) = 0.28, p = 0.76$) or Total Steps ($F(2, 91) = 1.01, p = 0.37$) in the pretest metrics. There was a marginally significant difference between the groups for accuracy ($F(2, 91) = 2.38, p = 0.09$), but this is not a meaningful difference due to the few number of steps in the pretest and the Choice's group lower average number of steps. Therefore, we concluded that each group had a distribution of students' with similar incoming proficiency.

For the training and posttest performance metrics, ANCOVA was used controlling for pretest metrics. There were no significant differences between any performance metric in the training portion of the tutor (Total Time ($F(2, 90) = 2.07, p = 0.13$); Total Steps ($F(2, 90) = 1.84, p = 0.16$); Accuracy ($F(2, 90) = 1.34, p = 0.27$)). The posttest metrics show a significant difference in the Total Time ($F(2, 90) = 5.24, p < 0.01$) between the groups. Tukey Contrast analysis revealed that there was a significant difference between the Assertion and Choice group ($p < 0.01$); however, there was not a significant difference between the Choice and Control ($p = 0.29$) or the Assertion and Control ($p = 0.19$). There was no significant difference between the Total Steps ($F(2, 90) = 2.09, p = 0.13$) or the Accuracy ($F(2, 90) = 0.05, p = 0.95$) between the groups.

These results provide support for H_1 that the students in the Assertions group would perform similarly to the Control group; however, the Control group did not perform worse in the training as expected in H_3 . These results along with the results in 2 confirm H_1 . Assertions reduced help need without harming performance. These results provide evidence

Table 3: Pretest, Training and Posttest performance metrics for the Assertion, Choice, and Control groups.

Test	Metric	Control <i>n</i> = 29	Choice <i>n</i> = 27	Assertion <i>n</i> = 38
		Mean(SD)	Mean(SD)	Mean(SD)
Pretest	Total Time (min)	5.8(7)	4.0(2)	6.5(6)
	Total Steps	15(30)	9(7)	11(13)
	Accuracy	40(14)	35(14)	43(17)
Training	Total Time (min)	137(50)	114(49)	122(62)
	Total Steps	374(126)	348(124)	323(118)
	Accuracy	63%(12)	66%(11)	66%(10)
Posttest	Total Time (min)	37(29)	43(34)*	34(20)*
	Total Steps	104(56)	129(75)	102(47)
	Accuracy	69%(12)	69%(11)	69%(11)

in support of H_2 ; however, these results do not address why the Choice group performed worse. One theory is that the students could have been making poor self-regulated decisions, supported by Table 2, which may have made them perform worse than the Control even though they both had a choice. The prompts may have lead to the Choice group to make more help-seeking decisions than the Control, where students would have thought about hints less. However, the questions asking whether or not they would like a hint could have also been frustrating or distracting. This distraction could have caused them to lose focus; however, we would have expected the total time in the training to be significantly different in that case.

Lastly, one of our concerns was whether students were better at self-regulating than a random proactive policy. The Assertions group was the slowest in the pretest, but they were the fastest in the posttest, shown in Table 3. Their overall hint Justification rate was also high, shown in Table 1. Along with the results confirming H_1 in the Table 2 and Table 3, these results suggest that the Assertions group with unsolicited, tutor-initiated hints did no harm to students in terms of learning outcomes compared to the Control group and produced better learning outcomes than the Choice group. Therefore, these results suggest that proactively adding hints at the very least did no harm.

5 Conclusion

This work contributes an investigation of the effects of three groups with varying levels of autonomy of assistance on learning outcomes and metrics to evaluate hint usage and hint avoidance. The three groups from most autonomous to least: 1) Control, where students could request on-demand hints, 2) Choice, where students were periodically asked if they would like a hint, and 3) Assertions, where hints were periodically added to the student's workspace without any element of student choice. This study sought to determine whether students' autonomy over when and how the interface provides hints affects hint utilization and, in turn, overall success. Our results show that the Assertion and Control group produce similar learning outcomes; however, the Choice group performed worse on the posttest. Overall, our results suggest that unsolicited hints can effectively ensure that more help is delivered when it is needed, reducing autonomy without reducing learning. These results demonstrate that with an effective, machine-learned proactive hint policy, better learning outcomes are possible.

ABSTRACT

Recently, Crisis Management Serious Games (CMSG) have proved their potential for teaching both technical and soft skills related to managing crisis in a safe environment while reducing training costs. In order to improve learning outcomes insured by CMSGs, many works focus on their evaluation. Despite its great interest, the learner emotional state is often neglected in the evaluation process. Indeed, negative emotions such as boredom or frustration degrade the learning quality since they frequently conduct to giving up the game. This research addresses this gap by combining gaming and affect aspects under an Educational Data Mining (EDM) approach to improve learning outcomes. Therefore, we propose an EDM-based multimodal method for assessing learners' affective states by classifying data communicated in text messaging and facial expressions. This method is applied to assess learners' engagement during a game-based collaborative evacuation scenario. The obtained assessment results will be useful for adapting the game to the different players' emotions.

Keywords

Serious game, crisis management, assessment, educational data mining, affective states, multimodal emotion detection.

1. INTRODUCTION

Recently, Serious Game (SG) development and usage have increased to improve learning benefits and to increase learners' motivation [1]. SGs applications reach out several domains such as crisis management, education, ecology, and health-care [2]. Indeed, collaborative Crisis Management Serious Games (CMSG) have proved their potential for teaching concepts related to managing different types of crisis situations such as natural disasters (earthquakes, floods), man-made disasters (terrorist

attacks, pollution), and technological crises (industrial accidents, cyber attacks) in a fun way while reducing training cost and saving time [3].

Despite its obvious interest, the exploitation of the SG concept in learning processes is not always a guarantee of its effectiveness [4]. As any learning systems, SGs rely on the implicit alignment of the learning outcomes (knowledge or skills) and the game experience (engagement, motivation). In particular, the effectiveness of a collaborative CMSG depends on different learners' characteristics including cognitive, emotional and social aspects [4]. Consequently, there has been a lot of research focused on the evaluation of SGs and their effectiveness for Crisis Management (CM) training varying in terms of crisis situation, number of players, key indicators or characterization of learners [5,6,7,8,9,10]. However by studying the state of the art, we have noticed that there is a considerable lack of studies integrating the concept of affective computing, especially learners' affective states, in the evaluation process within collaborative CMSGs [4]. Besides, most of existing works use explicit techniques for analyzing learners' behaviors during playing like pre/post questionnaires, interviews and debriefing sessions. These techniques represent a subjective evaluation that relies on non-exhaustive players' opinions and disrupts the high level of engagement provided by the game; impacting thus negatively the accuracy of evaluation results [30]. So, improving players' engagement (and thus learning outcomes) requires detecting and assessing such emotional states in a non-intruding way [11].

In this paper, we focus on addressing this gap. In doing so, we focus on the detection and analysis of learners' emotions expressed in textual and visual data to infer Flow game-play experience indicator (also called engagement) in collaborative CMSGs. To the best of our knowledge, players' engagement measure and impact on learning outcomes have not been investigated in such context. Hence, our contribution is to propose an emotion-based EDM method able to:

- 1) Assess the temporal dynamics of learners' affective states during a game-based session for CM training.
- 2) Evaluate their final states at the end of training process by classifying data communicated in text messaging and facial expressions.

Ibtissem Daoudi, Erwan Tranvouez, Raoudha Chebil, Bernard Espinasse and Wided Lejouad Chaari "An EDM-based Multimodal Method for Assessing Learners' Affective States in Collaborative Crisis Management Serious Games" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 596 - 600

- 3) Explore the final individuals' affective profiles to generate the group emotion at a global level.

The rest of this paper is organized as follows. Section 2 presents the proposed EDM-based multimodal method for learners' affective states assessment. Section 3 reports the application of our method on a collaborative CMSG used as a case study. Section 4 discusses our major findings. Section 5 summarizes the paper and presents our plans for future work.

2. AN EDM-BASED MULTIMODAL METHOD FOR ASSESSING LEARNERS' AFFECTIVE STATES

Our aim is to develop an automatic method for assessing learners' affective states (*engagement, frustration, confusion, and boredom*) using facial expressions and text analysis in collaborative CMSGs. To reach this objective, we need to perform five main steps corresponding to specific tasks namely *data collection, data annotation, data fusion, data analysis, and data visualization* as illustrated in Figure 1.

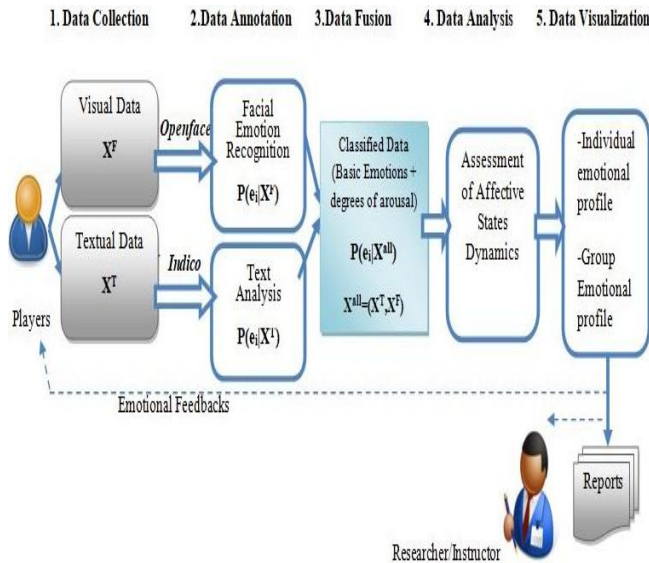

Figure 1 General Overview of the Proposed Method

2.1 Data Collection and Annotation Task

In order to collect data in a way that is more efficient and less intrusive compared to physiological measurements [12], we plan to extract the *messages* exchanged between players as well as the *video records* of learners' faces produced in real-time using a Webcam. These two kinds of data are annotated as follows:

- **Text annotation.** The textual content of these messages represents a rich source to detect their emotions that are revealed by the annotator tool *indico.io*. It is a predictive analytics tool classified as one of the top AI APIs for emotion detection from raw text strings (shorter instances of text like conversations) using deep learning algorithms with 93.5% of accuracy [13]. The API gives as an output the probability that the text reflects the basic emotions as well as their intensities.
- **Video annotation.** We have adopted *Openface 2.0*[14]: an automatic facial behavior analysis and understanding toolkit. Openface returns intensity and presence for each Facial Action Unit (FAU) estimated with several computer vision and machine learning algorithms. We

exploit the output of FAU recognition system since it displays emotions according to [15]. Based on the EMotional Facial Action Coding System [16], mapping rules associate couples of FAU with basic emotions. For example, *joy* is associated with detection of *Cheek raiser* FAU and *Lip corner puller* FAU.

2.2 Data Fusion Task

In our study, we perform a multimodal fusion at the decision-level which refers to the process of combining data collected from many modalities after being pre-classified independently to obtain the final classification. In fact, each classified modality, using the previous annotators, provides one hypothesis on labeled emotion categories; and this integration method gives a global estimate based on partial results [17].

$X^{all} = (X^T, X^F)$ represents the global feature vector consisting of the text feature vector, X^T , and the face feature vector, X^F .

In decision-level fusion, two separate classifiers provide the posterior probabilities $P(e_i|X^T)$ and $P(e_i|X^F)$ for text and face, respectively, having to be combined into a single posterior probability $P(e_i|X^{all})$; where e_i represents one of six possible classes of basic emotions ($e_1=joy$, $e_2=sadness$, $e_3=surprise$, $e_4=anger$, $e_5=fear$ and $e_6=disgust$).

The face modality is assumed to be the main modality in our multimodal approach (but the text modality is not neglected). Hence, we assign weights as follows: $\mu_T=0.3$ for the text modality and $\mu_F=0.7$ for the face modality. We adopt this weighting proposed and validated by works referenced by [18] and [19]. Then, we apply the averaging formula using these weights in order to compute the average probability of the two modalities defined as follows [20]:

$$P(e_i|X^{all} = X^T \text{ and } X^F) = (\mu_T * P(e_i|X^T) + \mu_F * P(e_i|X^F)) / 2$$

2.3 Data Analysis Task

In this task, we perform a fine-grained analysis of the dynamics of learners' affective states based on facial features during playing by studying the impact of stress on affective transitions, and we produce a summative evaluation of their emotional states at the end of training process:

- **Stress detection.** The stress is one of the most frequently occurring emotions inherent to CM since it affects the actors' way to manage crisis situations [4]. Given stress is related to emotions; also facial expressions have been used to detect stress by linking some of basic emotions as features [21]. In fact, many works have proved that, in different contexts like driving and working environments, stress is detected if either anger, fear, or a combination of these two negative emotions is detected constantly within a fixed time interval [22,23]. In particular, they focus on some specific FAU and their activation level extracted in each video frame, described as an indicator for fear and/or anger.
- **Mapping between affective states and basic emotions.** Affective states are particular combinations of basic emotions as demonstrated by [24] using association rules mining. In our study, we adopt the existing mapping as described in [24, 19]; and we propose some novel interpretations of basic emotions combinations

allowing us to deduce affective states based on existing theories of emotions [15,26].

Flow/engagement is defined by a high level of *surprise* and a low *sadness* level [19]. Since joy and sadness are opposite emotions as validated by [15] and flow is characterized by a full involvement and enjoyment in the activity [26], we can affirm that *flow* can be defined also by a high level of *surprise* and a high *joy* level.

Frustration is detected at the presence of a high degree of *anger* and a low degree of *joy* [19]. Likewise, frustration can be defined by a high level of *anger* and a high *sadness* level. Moreover, basing on the definition of frustration state [26], it can be mapped to a high level of fear as well as a high level of sadness. In the same way, frustration can be defined by a high level of *fear* and a low level of *joy*.

Boredom can be mapped to a high level of *disgust* as well as a low level of *joy*. In the same manner, *boredom* can be defined by a high level of *disgust* and a high *sadness* level [19].

The state in which *all the levels of six basic emotions* are low will represent the *confusion* affective state [19].

2.4 Data Visualization Task

This final task concerns visualization of our analysis results at two levels: individual and global. On the one hand, we visualize the summative individual emotional profiles which contain relevant information about affective states expressed by each player at the end of training process by selecting the dominant and the most pronounced emotion. On the other hand, we visualize the aggregation of all individual emotional profiles based on a decision tree algorithm to decide on the *polarity* of global emotion (*positive* or *negative*) and then to constitute the group emotion [27]. So, we apply *J48 decision tree classifier*, an implementation of *C4.5 algorithm* in *Weka*, to generate a decision tree on the group emotion based on individual affective states with a default confidence value=0.25. The principle is to decide the class label of group emotion (*positive* or *negative*) by learning decision rules inferred from training data (rates of individuals affective states). According to our experimental results, this tree-based method reaches an accuracy of 81% using *5-fold cross-validation*. Figure 2 shows the decision tree model of group emotion.

Figure 2 Decision Tree Model of Group Emotion

3. EXPERIMENT AND RESULTS

3.1 Game Description

We have developed a collaborative scenario for building evacuation training in case of a fire emergency situation. This scenario is implemented on the iScen software platform [29], specifically intended for crisis simulation, management and training. The scenario aims to train people (staff or students) of a Tunisian university building on evacuating all the present persons during a fire emergency triggered in the coffee shop as shown in Figure 3. The evacuation exercise involves a group of 30 participants (including player and virtual characters) having different roles namely *coordinator*, *security responsible*, *firefighter*, *warden* and *deputy* who must collaborate and coordinate their actions in order to manage an emergency evacuation procedure. This scenario allows learners to reach two main pedagogical objectives consisting of: (1) acquiring personal fire safety skills both in general and specifically in a university context, and (2) teaching best evacuation practices required to manage any fire emergency in an efficient and rapid manner.

Figure 3 Screen Capture of Crisis Situation

3.2 Dataset

We analyze (n=30) students' behavior trace interaction data obtained after the game session that lasts approximately 25 minutes. These data are video recordings of the participants' faces while playing using webcams as well as exchanged messages using the text chatting system. We analyze affective dynamics experienced by participants by tracking emotions at a fine-grained level using facial features. We make judgments on what affective states were present in each 20-second interval basing on the mapping described above. In addition, pre- and post-test questionnaires were completed individually by all students before starting the game session (pre-test) and immediately after finishing it (post-test). Pre-test questions address personal information concerning prior game experience and CM knowledge. Learners are then categorized as *novice*, *intermediate* and *expert* to be confronted afterward to the experimental results. Post-test questions aim to measure the level of engagement based on the Game Engagement Questionnaire. Both pre-test and post-test are on a 5-point Likert scale ranging from 1 (not at all) to 5 (extremely).

3.3 Obtained Results

Comparing to several predictions proposed by the Cognitive Disequilibrium Model [24], it appeared that some of these predictions have been validated while others not addressed by the model are identified by our method. This model addresses transitions between affective states of learners while solving complex activities in relatively short learning sessions [24].

The supported predictions include the transitions from the state of engagement into confusion, confusion into frustration, and frustration into boredom which naturally occurred. In fact, analyzing transitions between affective states are so important because they provide insight into how learners enter into an affective state since engagement and confusion is correlated with higher performance, while frustration and boredom are correlated with poorer performance.

The two predictions that have been identified, but were unexpected in the model, include the transitions from frustration to confusion and boredom to frustration. First, even though the transition from frustration into confusion occurred rarely, we believe that some frustrated participants, could view the situation as a challenge and become more energized; and ultimately enter the confusion state while trying to resolve the current misunderstanding. Second, the transition from boredom into frustration occurred significantly when we detect a high activation level of some FAU characterizing the stress emotion. To resume, our findings suggest that some aspects of the cognitive disequilibrium model might need refinement and some transitions can occur due to a specific characteristic of the context of CM training namely the stress.

When aggregated across the all participants at the end of training process, our results indicated that 25% of learners felt engagement, 50% expressed boredom, 25% felt frustration, and 0% experienced confusion. Figure 4 displays a global view of the all individual affective states. This global view allowed us to decide the polarity of group emotion by applying our decision tree model. Hence, we can deduce that the global emotion is negative ($25\% \text{ engagement} + 0\% \text{ confusion} + 50\% \text{ boredom} + 25\% \text{ frustration} \Rightarrow \text{negative class}$).

Figure 4 Global View of Individual Affective States of Players

3.4 Results Validation

For validation purpose, summative evaluation results are compared to the answers to the Game Engagement Questionnaire (GEQ) analyzing self-reported subjective descriptions and collected after the game session. This questionnaire is one of the most commonly used self-report questionnaires in the player experience field for measuring engagement specifically elicited while playing games [28]. The core module of GEQ is a 33-item scale which is designed to measure game players' experience across seven dimensions namely *Immersion*, *Flow*, *Competence*, *Positive Affect*, *Negative Affect*, *Tension*, and *Challenge*. Dimension scores are computed as the average value of their items. The descriptive statistics obtained from learners responses are reported in Table 1.

Table 1 Descriptive statistics for dimensions of the GEQ

Dimension	Mean	Standard deviation	Max	Min
-----------	------	--------------------	-----	-----

Immersion	2.13	0.60	4.00	1.00
Flow	2.34	0.62	3.55	1.13
Positive affect	2.00	0.50	3.00	1.00
Negative affect	4.28	0.85	5.00	2.00
Tension	3.96	0.77	5.00	1.65
Challenge	3.43	0.68	5.00	2.00
Competence	2.43	0.56	3.00	1.20

4. DISCUSSION

As shown in Table 1, positive feelings are much less severe and less frequently experienced compared to negative feelings (lower than the mid-value of the scale). In fact, participants reported the level of *positive affect* to be low (2.00). More specifically, results analysis shows that *immersion* (reflecting how players felt strongly connected with the game) and *flow* (indicating whether players lost track of their own effort and/or the passage of time during the game) receive respectively average degrees (2.13 and 2.34). The dimension *negative affect* receives the highest value of all (4.28). This result indicates that playing the game engendered some negative emotional experiences in particular boredom. In addition, participants experience a certain high degree of *tension* (3.96) in the form of specific negative emotions like frustration. Moreover, in terms of *challenge*, participants report that the game environment is difficult and challenging (3.43) according to their level of *competence* (2.43). All these results confirm the negative group emotion detected after the application of our method on the same CM scenario. Basing on this result, we can conclude that the team performance is also negative. In fact, this interpretation can be explained by the fact that all participants are situated, for the first time, in an emergency evacuation procedure based on a virtual training environment. It can also be a consequence of limited learners' guidance and assistance carried out by the instructor during the training process in order to better achieve the game objectives.

To summarize, the final affect annotations obtained via our method correlate well with subjective responses to the GEQ. In comparison to the GEQ, our method represents an objective and rapid manner to analyze learners' emotions and to infer their affective states without distracting them from game-play using EDM techniques. Hence, our contribution is intended to support learning, maintain motivation, and increase learners' engagement in the virtual world of the game.

5. CONCLUSION AND FUTURE WORK

This paper investigates a multimodal learner analytics approach to assess emotional states in collaborative CMSGs. Specifically, decision tree models were trained to predict learners' affective states utilizing bimodal data including textual messages and facial expressions. Affective states predicted by the model are evaluated with learners' self-reported engagement scores reported after the game session. In future work, we want to extend this study to a larger sample of participants within another multi-players CMSG which is currently under development using Unity 3D game engine. Furthermore, we plan to analyze the quality of social interactions during a collaborative game session in order to more deeply understand the dynamics of affective states over time.

6. ACKNOWLEDGMENTS

The authors would like to thank EVERSIM (Simulation & Serious Games) society for providing them the iScen platform and assisting them in its use.

ABSTRACT

The increasing complexity in software development leads to the necessity for a detailed data analysis. Literature illustrates a stronger research focus on Educational Process Mining (EPM) being applied to the fields of e-learning and professional training. In this work, the opportunities of Process Mining (PM) are further examined by the evaluation of software engineering (SE) courses. The methodology follows the five stages of the *L* life cycle model* for PM projects using data from software repositories. The event log data was analyzed with the PM tool Disco to examine the students' work following an agile development process. The new tool *GitLab Analyser* supports supervisors to visualize educational processes and still extracts event logs for the further analysis and application of PM techniques.

Keywords

data mining, educational process mining, software engineering, agile development, Git, GitLab, education, software repositories, Innovation Lab, Scrum

1. INTRODUCTION

Within the last decades an enormous increase of research interest associated to the field of machine learning systems was observed [7]. Especially during the last ten years, the public interest in the impact of applied machine learning and data analysis methods further grew [6]. The massive increase and demand of new software functionality in these fields also lead to higher software complexities. Dealing with these complexities is difficult especially when it comes to innovations. For the development process of innovative software, time-to-market is a relevant factor due to its impact on revenue and business success of companies in comparison to their potential competitors [9].

In order to cope with the raised complexity Version Control Systems (VCS) were deployed in software development. Ad-Philipp Dumbach, Alexander Aly, Markus Zrenner and Bjoern M. Eskofier "Exploration of Process Mining Opportunities In Educational Software Engineering - The GitLab Analyser" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 601 - 604

ditionally, time-boxed plans, IT systems like content management systems as well as issue trackers are now widely used [1, 9].

Those systems also become more and more important for the educational domain. In practical SE courses, students learn and use such systems in order to better structure their development process as well as become prepared for their future employments. Research picked up on this development and started to explore PM opportunities regarding the evaluation of educational software development teams in order to improve the learning process. By extracting event logs from the software development projects, critical processes can be identified and improved.

Tools for Educational Process Mining:

Different tools for extracting, visualizing and analyzing event logs for educational purposes were introduced in literature. One solution called *SoftLearn* is mentioned in the work of Vázquez-Barreros et al. [3] and allows the visualization of the students' learning paths by offering a graphical user interface (GUI).

A publicly available solution is the platform *PHIDIAS* presented by Awatef et al. [2]. This tool provides a service for data and process mining to educational experts. It supports the reconstruction of educational processes and the detailed analysis of social networks.

Sokol et al. [11] introduced a web application called *MetricMiner* for mining software repositories and supporting researchers with the data extraction and statistical inference. Another analysis tool in the application area of Git repositories is *Gitinspector*. This tool is not directly defined as a PM tool, but supports creating insight into development processes by analyzing Git logs and delivering details about the author's contribution over time [5].

Despite all those approaches, Bogarin et al. [4] underline the lack of tools supporting educational specialists from various fields in analyzing educational processes by providing an easy to use tool and a generic framework for EPM in the context of SE courses. Many of the tools demand special knowledge in fields which educational specialists lack.

Applications of Educational Process Mining:

Bogarin et al. [4] summarized various application domains of EPM, which are listed in Table 1.

Table 1: Application areas for EPM [4]

Application field	Amount of studies
Massive Open Online Courses, hypermedia learning environments, learning management systems	8
Computer-supported collaborative learning	5
Professional Training	5
Curriculum Mining	3
Computer-based assessment	2
Software repositories	2

In these applications EPM is used to discover learning flows and sequential patterns. Participants’ decision-making processes as well as usage of group communication tools are analyzed to detect learning difficulties. Consequently, the quality of education can be improved by adapting the educational software development process based on the analysis results [4].

Mittal et al. [8] introduced a holistic approach to evaluate the complete educational software development process. They present the idea for a research framework for PM using event logs of VCSs, issue tracking systems and team wikis. To the best of our knowledge, there is no tool available extracting all the relevant event logs necessary to feed this research framework.

Contribution

We contribute a tool called *GitLab Analyser*, which visualizes and extracts EPM relevant event logs from the open source software project management framework GitLab. The tool is easy to use not only for experts but also general educational specialists. Besides, it allows a holistic analysis over underlying learning processes by extracting event logs from the git software repository, the GitLab issue tracker and the GitLab documentation Wiki.

The *GitLab Analyser* is publicly available as standalone application under the following link:

<https://www.mad.tf.fau.de/research/gitlab-analyser/>.

2. METHODOLOGY:

For the development of the tool we aligned with the first three stages in the five stage process of the *L* life-cycle model* for PM projects as described in the PM manifesto: planning and justification, data inspection, event log extraction, analysis execution and result interpretation [12, 13].

Planning and justification: We planned to extract event logs from a SE course called *Innovation Lab for Wearable and Ubiquitous Computing* offered by the Machine Learning and Data Analytics Lab at the Friedrich-Alexander-Universität Erlangen-Nürnberg (FAU) over the last five semesters. The Innovation Lab is offered to various majors of the university’s technical faculty. In this course interdisciplinary student groups of size five to eight develop innovative software related prototypes in cooperation with multiple industry partners and public institutions. Over four months, these teams use the agile development process Scrum [10] and perform three Sprints after an on-boarding phase.

Data inspection: As a project management tool, GitLab

Community Version 12.8.0 was used because it offered

- planning features (milestones and issue tracker),
- versioning of the source code and
- documentation features (Wiki).

Both the VCS of the source code as well as the Wiki are git repositories. From all those features events describing the development process can be extracted.

Event log extraction: The events of the VCS and the Wiki were extracted using the git native ‘git log’ command. Events related to the planning features (milestones, issues) were extracted using GitLab’s native API and the REST API client postman. After extracting the events, they were converted to a .CSV file, which can be interpreted by commonly used PM software like Disco or Celonis.

Table 2 summarizes the data set out of the Innovation Lab projects at FAU, the tool was developed with.

Table 2: FAU GitLab log data

GitLab General Information	Value
Number of projects	24
GitLab issues	3409
GitLab repositories commits	5332
GitLab wiki commits	8474
Number of project branches	744

3. RESULTS AND DISCUSSION

3.1 Event Logs for Process Mining

Table 3 gives an overview about the majority of events and activities concerning the planning in GitLab, tracking of source code changes in Git as well as the documentation of the project in Wiki.

Table 3: Events and activities considered in project development process

Planning	issues, issue labels, milestones, branches, merge requests, notes, projects
VCS	number of changed files, commits, commit type, inserted and deleted lines of code, days with commits, number of merges and merge requests
Documentation	inserted and deleted lines of code, number of wiki pages, commits, days with commits

Further indirect available events are extracted by mining the issue notes section e.g. *changed milestone*, *assigned to* or *time spent*. By extracting the data the minimum information about the event logs is collected (*instance id*, *activity*, *timestamp*, *actor*).

3.2 The GitLab Analyser

The *GitLab Analyser* is developed for the implementation as easy to use tool for general educational specialists and to visualize event logs for supervisors. The tool offers three different analysis types all aiming to support supervisors in evaluating students and the development process itself:

1. *Single project analysis:* Support for supervisors in evaluating students and the development process itself.
2. *Group project analysis:* Support for supervisors to compare the performance of different teams of the same course (given that all projects are hosted on the same GitLab server).
3. *Cross-project analysis:* Support for different courses to compare the development process by extracting event logs from different GitLab servers.

Within the tool different result views are presented to the user on a dashboard. A user view offers the analysis of project events performed by the individual users, whereas a project view provides insights into the overall project status.

Figure 1: Participation event distribution of users. Color coding: assigned to user (green); unassigned to user but still participated (red) and mentioned user and participated (yellow).

Figure 1 depicts an exemplary graph from the dashboard on the user view. This graph visualizes the number of events as a result of the issues students worked on during the development process and whether they were assigned to those issues. This example shows an even assignment rate with one exception, *Student 4*. Based on this visualization the supervisors can see students with less participated issues and act based on these results by providing additional help to the student in case of lack of background knowledge, breaking big issues down into smaller issues to increase the student's success or motivation.

Figure 2: Inserted (green) and deleted (red) code lines in commits and changed files (blue) per day.

Figure 2 shows a graph from the project view. This graph visualizes the number of added, deleted and edited software code lines committed to the VCS of all team members over time. It clearly shows a peak in the middle of the development process, which was due to a Scrum Review at this point in time. By inspecting this graph, supervisors can identify that students do not continuously push their code changes to the repository, which is necessary for other team members to work on a common base. Thus, they can motivate students to improve the development process by continuously committing their new developments to GitLab.

3.3 PM opportunities in university projects

With Celonis and Disco two PM tools were tested. The extracted and transformed event log data (from GitLab raw-log data) was exported and analyzed with Disco to support the identification of correlations in the development process. In the Wiki and Git analysis the commit behaviour and distribution of commit activities was identified. In addition to the visualization of issue states, performance measurements like the average working time on an issue or time until the first user assignment, were determined by the analysis of GitLab features. The participation on issues as well as the information about users carrying out an activity at a specific point in time can be visualized. The time-boxes filter options in Disco enable to use the event logs for precise analysis of activities occurring for example within one Sprint. Furthermore, Disco offered options to analyze specific process parts by filtering the individual and process-relevant activities.

Figure 3: Process Map - Status changes of issues (100 percent activities, 50 percent paths)

Figure 3 illustrates the analysis of assignment activities in form of a process map as an exemplary Disco visualization. The investigation shows the total number of issues being assigned before their closing, i.e. whether a team member was responsible for them. Additionally, the number of assignee changes can be viewed, represented by the self-referencing arrow at the "assigned to" activity (12 times), and used as indicator for evaluating the team performance.

The event log extraction allowed to gain insight into the

students' work following an agile development process. Nevertheless, the analysis and filter configurations in Disco require a certain training period. It was critically questioned whether scientific staff, performing the role as Scrum Master not as a data scientist, need to familiarize themselves with the deeper functionality of PM analysis. Instead, course supervisors should be enabled with a tool to obtain essential analysis results with less effort in a short amount of time.

4. SUMMARY AND OUTLOOK

Due to the increasing complexity in the software development process the application of PM techniques offers valuable opportunities especially in the education domain. Various studies underlined the necessity for tools supporting educational analysis following an agile development process [4]. We introduced a standalone, easy to use tool called *GitLab Analyser* which can be used by supervisors from various fields without significant background in computer science. The tool not only offers the event log extraction for a detailed PM analysis using elaborate PM software (e.g. Disco, Celonis), but also visualizes the individual event logs in clear way for supervisors to evaluate students and the development process quickly. We made the tool publicly available under the following link:

<https://www.mad.tf.fau.de/research/gitlab-analyser/>.

The *GitLab Analyser* will be used within the upcoming semester of the Innovation Lab by the supervisors of the different development teams for immediate feedback on the development process. Additionally, the first version will be available for supervisors of other universities with similar courses to receive feedback and first bug reports for the next iteration of the tool development process.

Besides, we will use the tool to extract event logs from the last five semesters of the FAU's Innovation Lab and other comparable innovation courses of cooperating universities. By finishing the *L* life-cycle model* for PM projects through performing analysis execution and result interpretation, we will evaluate students' development and learning processes in order to come up with recommendations for improved teaching.

5. ACKNOWLEDGMENTS

The authors would like to thank the Zentrum.Digitalisierung Bayern (ZD.B) for funding the *Innovation Lab for Wearable and Ubiquitous Computing*. We thank Prof. Dr. Gerd Beneken and Martin Kucich from the Rosenheim Technical University of Applied Sciences as well as Prof. Dr. Daniela Nicklas and Simon Steuer from the University of Bamberg for sharing their expertise regarding the conduction of SE courses and supporting the increase of project data for the upcoming steps.

Bjoern M. Eskofier gratefully acknowledges the support of the German Research Foundation (DFG) within the framework of the Heisenberg professorship programme (grant number ES 434/8-1).

Comparing and Combining Tests for Plagiarism Detection in Online Exams

Edward F. Gehringer, Xiaohan Liu, Abhirav Dilip Kariya, and Guoyi Wang
North Carolina State University
{efg, xliu74, akariya, gwang25}@ncsu.edu

ABSTRACT

Online exams with machine-readable answers open new possibilities for plagiarism and plagiarism detection. Each student's responses can be compared with all others to look for suspicious similarities. Past work has developed several approaches to detecting cheating: n -gram similarity, Levenshtein distance, Smith-Waterman distance, and binomial probability. To that we add our own term-frequency based approach, called the "weirdness vector," which measures how unusual a student's answers are, compared to all other students. Each of these approaches seems suited to particular question types. Levenshtein and Smith-Waterman are suited to long text strings, as appear in answers to essay questions. Binomial probability and n -gram similarity are well suited for finding suspicious patterns in responses to multiple-choice questions. The "weirdness vector" is most applicable to fill-in-the-blank questions.

Unlike past research, that applied a single metric to detect cheating in an exam with questions of a single type, this paper measures how different approaches work with different kinds of questions, and proposes methodologies for combining the approaches for exams that consist of all three kinds of questions. This work shows promise for detecting cheating in open-web exams, where students can cheat using covert Internet channels, and is especially applicable in situations where exams cannot be proctored.

Keywords

Online exams; plagiarism; Levenshtein distance; n -grams

1. INTRODUCTION

Online exams have become more common in recent years due to the growth in online courses, especially after the transition to emergency online instruction. They have the advantage of faster grading, especially for distance ed, more copious feedback, and they can provide a more authentic testing environment by allowing students to access certain

information from the web (e.g., the course notes) during the exam.

Yet open-web exams do raise concerns about cheating [1]. Browsers can be locked down, and students can be monitored remotely with cameras [2]. But monitoring is expensive, and locking down browsers may destroy the authenticity of the environment. For example, in a course on open-source coding, students would always do their work online. If they don't have access to the Internet during an exam, they must work in an environment far different from their usual one. However, an authentic testing environment can only be used if there is a way to detect plagiarism.

Our approach is to use data mining to measure the similarity of the submitted answers. We extend our past work [3] by incorporating additional published tests into our application, and studying their applicability to different types of questions. Section 2 covers tests that have been proposed by others. Section 3 introduces new techniques for handling particular kinds of questions. Section 4 reports our findings from experiments on real data, and discusses which metrics are suitable for which types of questions. Section 5 summarizes our work and points out ideas for future progress.

2. RELATED WORK

Many published papers address automated detection of plagiarism, but with few exceptions, each paper focuses on a single mathematical test. While a few papers [4] do consider multiple tests, they do so in the context of comparing competing tests for detecting plagiarism on a particular kind of question (e.g., multiple choice). Since exams contain many different kinds of questions (multiple choice, essay, fill in the blank, matching, etc.) what is needed is a single application that can apply appropriate tests to responses to different kinds of questions. That is the goal of our research.

2.1 Levenshtein Distance

The Levenshtein distance between two strings is the minimum number of edits required to change one string into the other. For example, the Levenshtein distance between "faculty" and "faulty" is 1, the Levenshtein distance between "sloop" and "sleep" is 2, and the Levenshtein distance between "country" and "countries" is 3. In the research of investigating whether a machine learning model based on a statistical method works better than a model based on a structural method, the Levenshtein distance was chosen to be the similarity measurement for the structural approach.

Edward Gehringer, Xiaohan Liu, Abhirav Kariya and Guoyi Wang "Comparing and combining tests for plagiarism detection in online exams" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 605 - 609

Levenshtein distance has been researched not only for traditional string match, but as a structural method in clustering-based machine learning models of plagiarism detection [5].

One limitation of Levenshtein distance in detecting plagiarism is that rearrangement of text produces a large Levenshtein distance, since Levenshtein distance is focused on one-character (or one-word) edits. Suppose that two students' answers, taken as a whole, bear little resemblance to each other, but they contain sequences in different positions that are highly similar. The Smith-Waterman algorithm can identify this.

2.2 Smith-Waterman Algorithm

The Smith-Waterman algorithm is another classical string similarity metric. It looks for similar local regions to identify optimal sequence alignments. For example, the best alignment of two sequences $X = \text{"abcbadb"}$ and $Y = \text{"abdbd"}$ would be

```
a b c b a d b
a b - b - d b
```

Researchers have proposed alterations of the Smith-Waterman algorithm that were tested effective in practice of detecting collusion while speeding up the algorithm without using up much space [6]. Traditional Smith-Waterman algorithm searches through a pair of sequences and finds the maximum piece of consecutive matching characters, whereas the revised implementation introduces the cut-off concept to keep track of multiple pieces of matching. The modification yields more optimal local alignments and thus more effective on plagiarism detection as well.

2.3 n -grams

Another attempt from the structural perspective is n -grams. We can consider a word as a token [7]. Then an n -gram is a set of n consecutive words. Then for two exam submissions, we can ask what is the longest common n -gram between them, or how many n -grams of length $> k$ do they have in common? This is a useful metric for comparing two students' essay answers, but it also useful for comparing other kinds of answers, such as answers to multiple-choice (MC) questions. Here, MC answers, not words, make up the strings we are comparing.

MC questions have the property that the answers are chosen from a discrete set, usually about four in cardinality. Given that there are m possible answers for each question, the probability that two students will choose the same answer by chance is $\frac{1}{m}$. The probability that they will choose the same k consecutive answers is $\frac{1}{m^k}$. This is the idea behind the binomial test [8]; it is very unlikely that two students will choose a large number of the same wrong answers by chance.

Each of these methods works well on a specific type of text. A more comprehensive approach that works on all types of questions is needed for online exams. We will further analyze the effectiveness of each metric to determine which metrics work better for multiple-choice questions, fill-in-the-blank questions, and essay questions, respectively.

3. PROPOSED METHODS

3.1 The "weirdness" vector

The weirdness-vector metric looks for pairs of students who have similar but unusual answers. The basic idea is to calculate the term frequency of each response by each student and create a vector of term frequencies. Then we can use cosine similarity to measure the distance between the weirdness vectors of each pair of students. Those who have the most similar vectors are worth further inspecting.

3.1.1 Data Preprocessing

1. For the set of students $S = s_1, s_2, \dots, s_n$, we extract all their responses R into a matrix where $r_{i,j}$ is the response to question q_i by student s_j .
2. Then we remove the stop words and punctuation in the response matrix.
3. We use a function to classify each question on the exam as belonging to one of three question types: Multiple-choice, fill-in-the-blank, and free-response essay questions.

3.1.2 Implementation

1. For each response $r_{i,j}$ of student s_j to question q_i , we calculate its term frequency among all the responses to question q_i . Each response $r_{i,j}$ is converted into a "bag of words," and is compared with every other bag-of-words response to question q_i . The number of occurrences of each bag of words divided by the number of students n gives us the frequency $f_{i,j}$ of a response $r_{i,j}$.

$$f_{i,j} = \frac{\text{number of times } r_{i,j} \text{ appears in responses to } q_i}{n}$$

2. It is the low term frequencies that may be suspicious, but for the other tests in the program, high values are suspicious. Hence, we calculate the inverse term frequency instead:

$$w_{i,j} = 1 - f_{i,j}$$

3. Each student s_j has a "weirdness" vector W_j consisting of the inverse frequencies $w_{i,j}$ of each response to each question q_i , i.e., $W_j = w_{1,j}, w_{2,j}, \dots, w_{m,j}$, where q_1, q_2, \dots, q_m are the questions in the test.
4. We use cosine similarity to measure the closeness between pairs of weirdness vectors. For a pair of vector X and Y , the cosine similarity is calculated as

$$\text{cosine similarity} = \frac{\sum_{i=1}^n x_i y_i}{\sqrt{\sum_{i=1}^n x_i^2} \sqrt{\sum_{i=1}^n y_i^2}}$$

where x_i and y_i , $i = 1, 2, \dots, n$ are components of X and Y . The vectors with similarly high inverse frequencies will return high cosine similarity, for small values in the vector components do not contribute much when calculating the cosine similarity. That being said, only similar but unusual responses will stand out in similarity scores.

3.1.3 Regarding identical answers

The weirdness vector highlights suspicious behavior by detecting pairs of exams that contain identical incorrect answers, yet it is also worthwhile to identify pairs of exams that have identical correct answers. Some questions have multiple possible answers, where students can answer correctly without necessarily providing the exact same responses. Such cases can be well addressed by an algorithm that takes multiple correct answers into account; however, no algorithm can detect plagiarism among students who have provided the same correct response where only one correct response is possible.

3.2 Bag-of-Words Extension

Several metrics help detect plagiarism in text-based answers. Results can be enhanced by preprocessing the text before applying metrics. One kind of preprocessing is getting rid of stop words and removing punctuation. We can go one step further and treat the remaining words as an unordered set. This is the bag-of-words model.

3.2.1 Use Case

To illustrate the advantage of the bag-of-words model for finding similar answers, consider this example:

```
Response1 = "pattern: strategy"
Response2 = "strategy pattern"
Response1 == Response2 // False
bag_of_words(remove_stop_words(Response1)) ==
bag_of_words(remove_stop_words(Response2)) // True
```

Given that these responses are deemed incorrect, it is worthwhile to count the two wrong answers as matching. Without the removal of stop words and bag-of-words analysis, this case would go unnoticed as evidence of potential plagiarism.

4. EMPIRICAL RESULTS

The research questions that we are trying to answer are whether the tests can detect suspicious similarity, as well as which tests are most effective on each type of questions. We consider a test effective if it produces only a few unusual values (outliers) among its results. Of course, results from tests alone cannot be solid evidence of cheating; instructors would need to inspect the exam papers. To forestall excessive manual inspection, a good test should direct attention to the few most suspicious responses. If the observed values given by a metric contain outliers when it is applied to a particular kind of question, this metric can be deemed useful for that type of question.

We can use data visualizations to illustrate the effectiveness of all the metrics on three types of questions. We used real exam data from CSC 517 (all offerings between Fall 2014 and Spring 2020) at North Carolina State University. All data was de-identified before use.

4.1 Effectiveness of each metric

The weirdness metric shows us (Figure 1) how unusual it is for a pair of exams to share the same wrong answer to a question. Weirdness is a good test for FiB exams if only a few exams have a large number of the same unusual incorrect

Figure 1: Weirdness metric on 3 types of questions

answers. On essay questions, however, it is the responses with high term frequency that are suspicious, since each response should have its unique phrasing. Essentially, each incorrect essay response is considered “weird” and hence, the weirdness values will show a discrete distribution as shown in the histogram above. For MC questions, there is a much smaller number of possible choices, and thus, weirdness does not work as effectively as for FiB. Though both the FiB and MC weirdness values have small tails, the values are more meaningful for FiB questions.

Figure 2: Levenshtein on FiB and essay questions

The Levenshtein metric (Figure 2) uses edit distance to compute string similarity. While weirdness watches for short unusual responses for FiB questions, Levenshtein has its strength in detecting long similar responses for essay questions. As the histogram for Levenshtein performance shows, Levenshtein generates many fewer outliers on essay questions than on FiB questions. The essay histogram has a minor peak near 1.0, highlighting the responses that are suspiciously similar, whereas the FiB histogram has many high values, suggestive of false positives.

Smith-Waterman is pretty good at comparing long texts, and it is much more revealing on essay questions than on

Figure 3: Smith-Waterman metric results

FiB questions, as we can tell from the graph above.

Figure 4: Max n -grams metric results

n -grams are naturally suited to finding long similarities in essay questions. We can also concatenate all the MC responses of two students and use n -grams to compute the longest common subsequence between them. Since the number of pairs drops significantly after max n -gram length = 10 for essay questions, we choose 10 as the threshold and consider those greater than 10 to be outliers. FiB responses are much shorter, typically no longer than 7 words, and are expected to be mostly identical; thus n -grams are unlikely to provide much guidance. The max n -grams lengths of MC responses tell us how many consecutive MC questions two students answered identically.

The n -gram metric can, of course, help detect students who were collaborating extensively on MC questions, but it does not take correctness of the responses into account. Consecutive same correct MC responses should not be treated as suspicious.

Binomial is used for MC questions only, as it calculates the probability of students having the same wrong answers. It is a more reasonable metric for MC questions than n -grams because it does take correctness of responses into account.

4.2 The most suitable metric

Figure 5: Different metrics on MC questions

Figure 6: Different metrics on FiB questions

As discussed earlier, weirdness is much more applicable to FiB questions than other string matching metrics. The concave upward curve at (0.8, 1.0) justifies the effectiveness of weirdness.

Levenshtein, Smith-Waterman, and N -grams are all good metrics for essay questions, although empirically, Levenshtein is more effective over other tests.

5. SUMMARY

We can conclude from the empirical results that for multiple-choice questions, one should seek help from the binomial test. For fill-in-the-blank questions, weirdness works the best. For essay questions, Levenshtein, Smith-Waterman, and n -grams all work effectively.

ABSTRACT

This study uses skill-based curriculum analytics to mine the curriculum of an entire university. A curriculum profile is constructed, providing insights about university curriculum design and the match between one institution's curriculum and the job market for a cluster of data-intensive fields. Automating the delivery of diagnostic information like this would enable institutions to ensure that their professionally-oriented degrees meet the needs of industry, so helping to improve learner outcomes and graduate employability.

Keywords

curriculum mapping, curriculum profile, skill-based curriculum analytics, ontologies, skills profile, job market

1. INTRODUCTION

People around the world see universities as an important step in building a successful career [3]. They invest time and finances in undergraduate and postgraduate courses, with a goal to gain new competencies that will help them to find a job [2]. Over the decades, a number of institutions in the tertiary sector have worked hard to adapt their curriculum to market requirements, seeking to prepare more work-ready graduates. However, there is an ongoing debate about whether university efforts to develop students' skills have a noticeable influence upon graduate employability [18]. In particular, employers continue to express doubts that university education does indeed lead to professional

competence, claiming that it fails to provide students with the skills they actually require in the workforce [17]. At the same time, undergraduate employment rates are slumping [7], which often leads to further delays in the time it takes students to find work upon graduation, in turn leading to requirements for further professional training [10].

Until recently, much of this debate has been poorly supported by evidence and data. Claim and counterclaim prevail, but a large amount of the data supplied has been *ad hoc*, or cherry picked to support vested interests [20, 9]. However, with the rise of online job advertisements it has become possible to collect data about what potential employers demand in the workplace. A number of datasets can now be created, using data collected from web platforms such as LinkedIn¹, SEEK² and Monster³. Indeed, vendors such as Burning Glass (BG) technologies⁴ now market aggregation services and data that can be used to understand changing trends in the workforce. The next sections provide a brief overview of the ways in which this data can be used.

1.1 Curriculum analytics

Many attempts have been made to understand what gaps there might be in the curriculum offerings of educational institutions. For example, Knight and Yorke [13] describe the Skill plus project as an attempt to manually audit the university curricula for four universities and 17 departments. Trying to find curriculum gaps, Davis et al. [5] conducted a survey of graduates, Lang et al. [15] surveyed industry representatives, Lempp and Seale [16] conducted a study among health students. However, the manual and resultingly not sufficient scalability of this work, has limited the use of this work in linking to workforce needs [11].

Aleksandr Gromov, Andrei Maslennikov, Nikolas Dawson, Katarzyna Musial and Kirsty Kitto "Curriculum profile: modelling the gaps between curriculum and the job market" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 610 - 614

More recently we start to see data science techniques used to overcome these limitations. For example, attempts have been made to infer curriculum information from student performance and interactions with the curriculum [20, 21], but not the skills offered in the curriculum itself. *Skills based curriculum analytics* [12] makes use of Natural Language Processing (NLP) to map curriculum documents to a defined skills taxonomy, in this case for the purpose of recognising prior learning. A number of other works have made use of NLP in analysing curriculum [1, 8, 24, 19, 23], but only for specific subsets of curriculum (normally computer science). Thus, opportunities are emerging for automating the analysis of curriculum, but how might this be linked with labour market demand?

1.2 Connecting market demand and curriculum

Educational institutions have recognised their role in supplying market demand by offering various courses that prepare graduates to enter the workforce [4]. This transforms the problem of mapping curriculum into one of alignment with labour market requirements [14]. One of the most common methods applied to this task adopts industry skill frameworks and then formulate graduate attributes which match market expectations [14, 22]. This method allows curriculum managers and developers to see gaps, and work to align existing and new courses towards market expectations. It also helps students to plan their study course according to their career desires [25]. However, both frameworks and curriculum are living documents that adapt to the environment, and there is a time lag between acknowledging and implementing new skills and technologies into frameworks and curriculum. Furthermore, this curriculum mapping task is usually completed manually (see section 1.1, which makes it time-consuming, tedious, and prone to mistakes. Worse still, some industries may rarely update their industry frameworks, while other industries might not even have a formal listing of their skill requirements [6].

Overall, while many institutions make use of industry advisory bodies, market reports, etc. to map their curriculum by hand, we are yet to find examples of curriculum mappings to workforce requirements that are supported by the emerging large scale employment datasets that are becoming common in the field. This is the gap that we seek to address here.

1.3 Research questions and contribution

This work aims to use automated methods to map gaps between the subset of the curriculum taught at one institution and labour market demands. We will do this by asking the following three research questions:

- RQ1:** What is the skills profile for a complete institution?
- RQ2:** How can we explore the gap between university curriculum and market demand?
- RQ3:** How can we differentiate the match between contrasting curriculum pathways and labour market demand?

Our contributions include: (i) a preliminary method for automatically constructing a curriculum profile for an institution (ii) a way to compare subsets of curriculum within that institution (iii) a method for finding gaps between closely

related set of degree programs and the job market.

2. CURRICULUM PROFILE

This paper introduces the concept of a university curriculum profile. We make use of the BG ontology, which provides a static set of skills that can be consistently mapped into a range of different higher level clusters to extract information about what mix of skills is being taught across an entire institution. We chose the University of Technology Sydney (UTS) curriculum as a data source, which consists of 486 degree programs (termed courses) offered across 9 faculties at the undergraduate and postgraduate levels. In total, there are 3,739 subjects offered across these degrees. Information about the curriculum can be obtained using the UTS handbook (<https://www.handbook.uts.edu.au/>).

2.1 Method

This section discusses three experiments that have been performed, each designed to extract information about the skills taught at UTS. We start with a course profile across the entire curriculum of UTS in a bid to respond to RQ1 (Section 2.1.1), before performing a deeper analysis of the data analysis curriculum offerings at the same institution to respond to RQ2 (Section 2.1.2). Finally, in Section 2.1.3 we determine how well aligned these data analysis offerings are with local labour market demand, so responding to RQ3.

2.1.1 The UTS curriculum profile

For the first part of our analysis, we performed a skills analysis of the entire UTS curriculum, with a view towards developing a skills profile across the university. This then enables us to drill into sub-profiles for specific degree programs, demonstrating their similarities and differences. Our analysis implemented the following steps:

- STEP 1:** We scraped the UTS curriculum handbook.
- STEP 2:** Subject names and descriptions were mapped to lists of skills using the BG content tagger.
- STEP 3:** Skills were mapped to higher level skill clusters and families according to the BG Skill Ontology.

Drilling into the skill cluster families tagged by BG makes it possible for us to start exploring the distribution of skills taught by each Faculty at UTS. Encouragingly, this method reveals that the majority of the skills developed by each Faculty are in sensible skill cluster family domains, with some spread into other families, in explainable patterns. Thus, the Faculty of Engineering and Information Technology (FEIT) teaches 100% of all *Engineering* and 97% of all *Information Technology* skills covered at UTS; the Faculty of Health (Health) teaches the largest proportion of *Health Care* skills, followed by the Graduate School of Health (GSH); and the Faculty of Business covers the *Business* and *Finance* skills.

2.1.2 Within the data analysis curriculum

For our second analysis, we decided to perform a deep dive into a subset of the UTS curriculum. We chose to explore the Data Analytics related degrees available across UTS. This decision was based upon the existence of three potentially competing degrees that are currently offered at UTS

MDSI: Master of Data Science and Innovation (MDSI)

MIT: Master of Information Technology (Data Analytics)
MBA: Master of Business Administration (Data Analytics)

We sought to explore how much overlap existed in the curriculum associated with these three degrees, and whether there was a possibility that inefficiencies could be identified where the same skills were being taught across multiple subject offerings. We implemented this analysis by following a similar sequence to that presented in Section 2.1.1. Each of the three selected courses consists of a set of compulsory core subjects and an optional choices. We performed two separate analyses, extracting a skills profile for two different course structures: one using just the core subjects required for each of the three courses (core), and a second analysis that added the Data Analytics subject selections for that degree (data). We chose the IT, Business and Analytics skill cluster families for a further investigation of possible reasons of skills changes, because these are the claimed focus of the chosen degrees.

After skill profiling a number of patterns can be noted, for example, the MIT has the most complete coverage in the *Information Technology* skill cluster family, but has almost no coverage of the *Analytics* skills cluster family. However, adding the Data Analytics subject choices to the Core leads to an increase of skills in the *Analytics* skill cluster family (almost to the point where it has the same number of skills as the entire data science-oriented MDSI degree). Similarly, the Core MBA subjects cover all three skill families, but selecting more specific Data subjects leads to a growth in the number of skills in *IT* and *Analytics* skill cluster families. Finally, as expected given the exclusion of the full set of optional subjects no change is observed for the MDSI when expanding with Data subjects.

2.1.3 Finding a gap between market demand and curriculum offerings

For our final study, we combined UTS curriculum data with data about skills sought in the Australian job market:

STEP 1: We selected the top 10 Data Science and Analytics (DSA) skills, found by Dawson et al. [6] and required by the market, and checked if they exist in UTS curriculum and MIT, MDSI and MBA courses.

STEP 2: Then, we selected the top 10 DSA skills that showed the highest growth in the market and cross-checked to see if the UTS curriculum adapts to these rapid market changes.

STEP 3: After that, we selected three DSA Occupations from the BG ontology, retrieved the skills linked with these occupations in the BG ontology and compared them with the skills covered by the UTS curriculum.

Encouragingly, all of the top-10 DSA skills exist in the curriculum. However, some skills are missing from the selected Data Analytics courses. Overall, selected courses cover most of the demanded DSA skills.

At the same time, only four skills with the highest compound annual growth rate (CARG) in 2019 [6] exist in the resulting skills profile. Other technologies and tools, such as Blockchain, TensorFlow, Internet of Things, are missing in the curriculum we analysed. However, some of these skills

are yet to be integrated into the skills clusters and families of the BG ontology, which points to their very recent emergence. This gap points to an opportunity for UTS to identify rapidly growing skills that it considers beneficial to deliver: a curriculum gap that could be rectified.

Finally, we retrieved three DSA occupations (Data Analyst, Data Scientist and Business Intelligence Analyst) and their skills from the BG occupation ontology comparing them with the skills profiles for the MIT, MDSI and MBA (see Table 1 for the core subject selections). The results mirror those obtained in the previous section.

Overall, none of the UTS courses has more than 50% of the skills taught that required in our three selected occupations which potentially demonstrates a gap between university curriculum and market demand.

Occupation	Course	Both exist	Only in Occupation	Only in Course
Data Scientist	MDSI	27	73	97
	MIT	42	58	287
	MBA	37	63	153
Data Analyst	MDSI	20	80	104
	MIT	42	58	287
	MBA	34	66	156
Business Intelligence Analyst	MDSI	17	83	107
	MIT	35	65	294
	MBA	32	68	158

Table 1: Three DSA occupations from BG ontology with the number of skills existing and not existing in three selected UTS courses.

3. TOWARDS A CURRICULUM PROFILE

A number of findings about the curriculum taught at UTS emerge from the preliminary curriculum profile presented in the previous section. Firstly, there is a gap between BG skill ontology and the UTS curriculum profile. However, UTS develops knowledge not just software skills. The analysis shows only seven families are more than 50% covered by the UTS curriculum (Business, Economics, Engineering, Environment, Legal, Media and Science). At the same time, the most well-presented in the curriculum IT and Health families cover only 25% and 38% respectively. The majority of skills in these families are missing. However, the reasons for the gap are interesting in themselves, including:

- 1. Novelty skills:** there is a lag between new skills emerging (e.g. TensorFlow, WebAssembly) in the market and their incorporation into curriculum offerings.
- 2. Legacy skills:** in contrast, some skills (e.g. COBOL, ALGOL and the early versions of Microsoft Server) are present in the ontology but not taught at UTS.
- 3. Generalised knowledge:** the role of universities is larger than that of simple skill development. We see evidence that UTS is developing generalisable knowledge, rather than the more specific skills.

Another finding from our approach is that the faculties at UTS do appear to have specialisations which largely match the subject materials we would expect to see taught in the faculty. Thus, for example, the Business Faculty has a focus on “Finance” and “Business” (87% and 73% of all UTS skills in this families), Faculty of Engineering and IT includes “IT”

and “Engineering” (97% and 100% of all UTS skills in this families) and Science Faculty prepares students in “Science and Research” and “Environment” (100% and 77% of all UTS skills in this families). Overall, the UTS curriculum profile demonstrates that the university tends to develop knowledge, not just skills and an ability to use specific tools.

3.1 Data Analysis projection on different courses

Figure 1: Number of skills in three courses (Core and Data selections) for three BG skill families.

All three selected DSA courses have unique skill profile and prepare different types of Data Experts. By selecting three Data related courses from three different faculties, we wanted to find out if the courses, offered across UTS, are repetitive and faculties lack collaboration. The results in Figure 1 show that each course has a different flavour which aims to develop different fundamental skills. The MDSI focuses on Analytical skills, the MIT focuses upon IT skills and the MBA is giving fundamental knowledge in IT, Business and Analytics. However, expanding the Core subject selection to DSA major, we see that: (i) MBA almost stopped developing business skills and focused on Analytics, which also resulted in the number of IT skills increasing. (ii) MIT becomes far more aligned with the Data Analytics skill cluster, with an accompanying increase in IT and Business skill development (iii) MDSI did not change the curriculum profile at all, which is related more to the extremely open course structure of the degree and the fact that this could not be captured by our method. Overall, each course prepared almost the equal number of skills in Analytics (39 for MBA, 43 for MIT, 44 for MDSI). However, the content and the student pathway are not the same. Students from MDSI are focusing on Data Analytics, as expected from a Data Science course, but MIT students have a strong background in IT, supported by Analytics. Finally, MBA students are well-rounded specialists in IT, Business and Analytics.

3.2 Finding a curriculum gap

The first gap revealed in section 2.1.3 illustrates a disconnection between the understanding of graduate capabilities possessed by universities and the market. While some skill sets are too narrow to be useful to a graduate (e.g. Atlas.ti and Alteryx), others are popular on the job skills for data analysts and data scientists (e.g. SQL and Git). A domain expert is required to make the distinction between these skills, but our method of building curriculum profiles could help with decision support, showing up skills that are essential but still largely unrepresented in the curriculum.

The second gap we found is a lag between the appearance of

a new area of knowledge in the labour market and its introduction to the curriculum. This gap should be distinguished from the emergence of new tools alone, although there can be some overlap (e.g. with TensorFlow and Apache Spark). More general skills like Deep Learning, Data Lakes and Random Forests also feature in this list. Similarly, there is a need for Internet of Things and Blockchain specialists which the UTS curriculum is yet to respond to. This second gap is potentially more dangerous because it shows incapability to cover new areas of knowledge in time. However, more analysis is required to investigate the actual demand for these emerging skills. For example, while the CAGR can be very high, this can be achieved by doubling the demand for a skill that was previously only advertised for twice in a time period. Care must be taken to disentangle growth from absolute demand, a task that we reserve for future work.

4. CONCLUSIONS AND FUTURE WORK

In this article, we introduced the university curriculum profile that allowed us to explore the skills taught across an entire university, and to establish that the faculties at UTS do indeed teach the skills we expect. It also enabled us to demonstrate the existence of a potential gap in what was taught, but which was explained by unearthing the too specific and technology dependent nature of many skills in the BG ontology. This gap was explained with the observation that universities should be developing graduates who can generalise knowledge from their skillsets, not just make use of a highly specific tool, and was therefore identified as not critical.

This work can be extended in several ways. Firstly, it will be important to find ways of representing the complexity of a curriculum structure using more than counts. Many of the potential gaps our analysis identified turned out to be understandable once we looked deeper into the skills that were not being taught (Section 2.1.3). Secondly, the analysis can and should be extended beyond the DSA degrees considered here to explore what differences may result from using different skill sets. Third, finding the curriculum gaps will benefit from the development of automated tools for finding changes in labour market demand. Such instruments could be tuned to track changes in real-time and provide historical data for more in-depth analysis of the university curriculum and its development. Finally, the current method of extracting skills from the curriculum cannot identify differences between novice and advanced skills. It is essential that we develop additional tools for evaluating these different levels of skill proficiency.

We believe that the method of profiling curriculum developed here will help institutions to adjust existing courses or initialise new ones as required by the market. It will also help students to choose more effective learning paths according to the market demand. As such, it has the potential to help institutions improve outcomes for all learners.

ABSTRACT

In recent years, Wiki has been proved effective for collaborative learning in modern education. As a typical collaborative writing system, Wiki empowers students in generating, modifying and structuring their own contents. Some courses may include these collaborative assignments like writing a wiki page as part of assessment. But for teachers, it is difficult to assess the quality of student contributions, because the final result of project is made up of edits from different students. In this paper, we propose a content-based model, OSEAN(Order-Sensitive Edit Assessing Network) to better address this problem. OSEAN can represent and predict students edits' quality by extracting semantic features from edit pairs. Experiment results show that OSEAN has the highest AUPRC on Wikipedia edit quality classification task in all tested methods. Furthermore, OSEAN can handle reversed edit pairs correctly, which often happens when one student undoes previous student's edit.

1. INTRODUCTION

In recent years, the use of modern information and communication technologies in education has been widely studied[10]. Thanks to the rapid development of web technology, higher level of collaborative learning becomes easier. Among these web applications, wiki attracted attention for enabling students work together. According to the definition on Wikipedia, wiki is a knowledge base website on which users collaboratively modify and structure content directly from a web browser. These inherent characteristics of wiki technology encourage students collaborate to create their own contents[3].

However, assessing student contributions in a wiki project can be difficult. This is because that students not only add

Tianyu Hu, Guangzhong Sun and Zhongtian Xu "Assessing Student Contributions in Wiki-based Collaborative Writing System" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 615 - 619

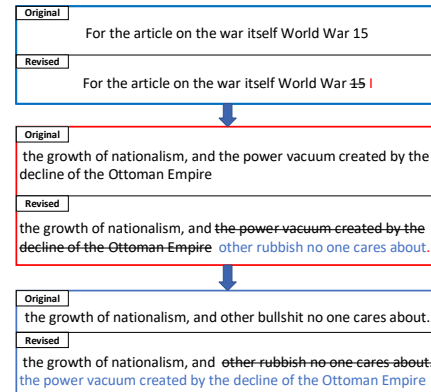

Figure 1: Example of revision history from Wiki page: Causes of World War I. We select 3 continuous versions and compare the differences. Edit 1 fixed an error in the page. Edit 2 deleted some words and added some offensive words. Edit 3 did a revert operation to eliminate vandalism information introduced by revision 2.

contents to the project, but also revise or delete contents which are added by others. Since reprocessability plays a key role in evaluation of student works[6], we should assess student contributions from the entire process of wiki project. If teachers only evaluate everyone's contribution from the final state of the project, then some important behavior information can be lost. Figure 1 gives an example of page revision history. In this work, we care about the quality of students contribution in the project, so we need to evaluate the quality of each edit. A wiki project usually consists of many edits, which brings a lot of works to teachers. Therefore, we want to evaluate the quality of edits in an automated way. To predict new edits' quality, two types of methods are proposed. Content-based methods extract features from the content of edits. ORES[5] and Stiki[11], web services provided by Wikimedia team, use linguistic features to compute the probability that a specific edit is damaging. StRE[8] utilizes deep neural network and achieves a high accuracy. On the other hand, content-independent methods, e.g. Interank[12], treat edit as the interaction between user and project(page).

While each edit is a pair of sequences before and after an edit, a new question arises: Does the order of pair matter? The order of edit pairs represents the direction of contents

evolution. If a model can truly predict the quality of an edit, it should generate a opposite label if we reverse the edit pair.

To better predict new edits' quality and handle the order of edit pair. In this work, we propose OSEAN(Order-Sensitive Edit Assessing Network), a content-based edit quality prediction model. OSEAN extracts each dissimilar part of two sentences and learn the vector representations for two parts. To handle the order of edit pair, we utilize the subtract result between two parts as the final representation of the entire edit.

2. METHODOLOGY

2.1 Problem Formulation

An edit $P = \{S, T\}$ on a particular page is a pair of original sentence S and revised sentence T . Each sequence is represented as a fixed length character sequence.

$$\begin{aligned} S &= \{S_1, S_2, \dots, S_M\} \\ T &= \{T_1, T_2, \dots, T_M\} \end{aligned}$$

where M is the length that can be manually set. Our task is to find a page-specified scoring function that maps each edit to a binary label:

$$f_{page} : P \rightarrow L, L \in \{0, 1\} \quad (1)$$

2.2 Model Architecture

Figure 2 gives an overview of OSEAN. We will introduce each steps in the model below.

Character Embedding. The first layer performs a character-level look-up where each character is represented as a d -dimension vector. The edit pair is converted to two matrices of dimension $m \times d$.

Convolution Step. After the character-level embedding, the sequences of embedded characters is provided as inputs of convolution layer, which computes an 1-D convolution over the embedded sequences. A convolution operation involves a filter with size h :

$$c_i = \tanh(w_c \cdot x_{i:i+h-1} + b_c) \quad (2)$$

As a result, each sentence is represented as a feature map of dimension $l \times d$, where $l = m - h + 1$.

Dissimilar Part Extraction. Since an edit is changes of page contents, the dissimilar part of two sequences should have higher weights on qualities. We utilize the method from [9]. In our model, the semantic unit of the sequence is the combinations of characters after the convolution operation, and we only care about the dissimilar part. To determine which part is *dissimilar*, we need to check whether a unit is semantically covered by another sequence.

First, we compute the similarity matrix $A_{L \times L}$ for feature maps C_S and C_T after the convolution step, each element

$a_{i,j} \in A$ is the cosine similarity between unit $C_{S,i}$ and $C_{T,j}$.

$$a_{i,j} = \frac{C_{S,i}^\top C_{T,j}}{\|C_{S,i}\| \|C_{T,j}\|} \quad (3)$$

Then we use the similarity matrix to calculate the semantic cover of $C_{S,i}$ by combining all units in the other sequence C_T .

$$\text{cover}(C_{S,i}, C_T) = \frac{\sum_{j=0}^L a_{i,j} C_{T,j}}{\sum_{j=0}^L a_{i,j}} \quad (4)$$

The result $\hat{C}_{S,i} = \text{cover}(C_{S,i}, C_T)$ can be used to calculate the proportion α of unit $C_{S,i}$ that is present in the other sequence. The value of α is the cosine similarity α of $C_{S,i}$ and $\hat{C}_{S,i}$. So the dissimilar part's can be defined as $1 - \alpha$. The dissimilar part $D_{S,i}$ for feature map unit $C_{S,i}$ is:

$$\alpha_i = \frac{C_{S,i}^\top \hat{C}_{S,i}}{\|C_{S,i}\| \|\hat{C}_{S,i}\|} \quad (5)$$

$$D_{S,i} = (1 - \alpha_i) C_{S,i} \quad (6)$$

After performing the above calculations for all units in C_S and C_T , we get two dissimilar parts D_S and D_T .

Edit Representation. We use a weight-sharing fully connected layer(FCL) to generate representation vectors E_S, E_T for each sequence. To obtain the final representation E_{final} for the whole edit, we perform a **subtract** operation on E_S and E_T . The edit vector E_{final} is used for quality classification with a sigmoid activation.

$$E_S = W_0 D_S + b_0, E_T = W_0 D_T + b_0 \quad (7)$$

$$E_{\text{final}} = E_S - E_T \quad (8)$$

$$r = \text{sigmoid}(W_1 E_{\text{final}} + b_1) \quad (9)$$

Here, r is considered to be the possibility that the edit P to be a beneficial edit.

2.3 Order of Edit Pair

Consider an edit $P = (S, T)$, we assume P to be a beneficial edit and labeled as 1. If we reverse the order of the edit pair, the label of the reversed edit $P' = (T, S)$ should also be flipped, meaning P' has a label 0. This is because the reverted operation on a beneficial edit should be considered to be a damaging edit. If the order of the pair can not be handled correctly, the model is very likely to classify two opposite edit P and P' to be the same label.

We give the definition of *order-sensitive* here:

Definition 1 (order-sensitive). *A model is order-sensitive if for most edit pairs, it satisfies: the model gives two opposite labels for edit P and its reversed version P' .*

Obviously, an ideal edit quality prediction model should be order-sensitive. Our proposed model is *perfectly* order-sensitive under ideal conditions which can be proven mathematically and also performed well in the experiment:

3. EXPERIMENTS

In this section, we conduct experiments to answer following questions:

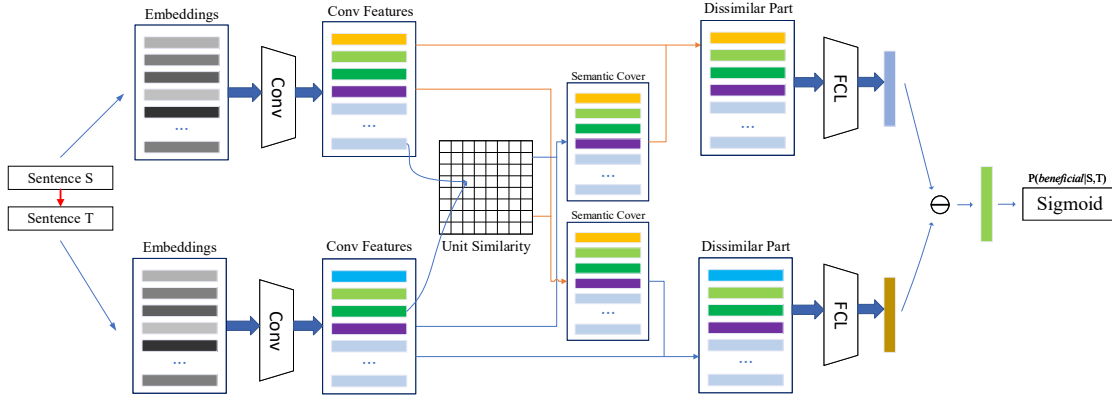

Figure 2: An overall architecture of OSEAN(Order-Sensitive Edit Assessing Network)

RQ1 Can our proposed model outperform state-of-the-art edit quality prediction methods?

RQ2 If the order of edit pairs is reversed, how the performance of all experimented methods will change? Can our model still maintain the best performance?

RQ3 If we add the order information to model training process by performing data augmentation, will model performance get improved?

3.1 Experiments Setup

3.1.1 Dataset

We evaluate model’s performance on the data extracted from Wikipedia page revision histories. As Wikipedia is the most widely used collaborative writing system in the world, experiments on this system can verify the effectiveness of our model. Page histories are divided into three categories:

1. CS: Pages containing top 147 pages with the highest number of edits related to computer science in English Wikipedia as of June 2017[8].
2. EN/ZH: Pages containing top 68/55 pages in the whole English/Chinese Wikipedia as of June 2019.

The number of samples in each category is reported in 1.

3.1.2 Computation of Edit Quality and Label

The basic idea is that if changes introduced by an edit is preserved in several subsequent edit, then the edit is considered to be beneficial. Otherwise, if the changes is reverted, then the edit is damaging. [1] and [2] give a formula to compute the proportion of preserved changes. We follow the approach and use a average value to compute the edit quality.

Consider a particular page and denote its k -th revision (i.e., the state of the article after the k -th edit) as v_k . Let $d(u, v)$ be the Levenshtein distance[7] between two sentences. We define the quality of edit k from the perspective of the article’s state after $\ell \geq 1$ subsequent edits as:

$$q_{k|\ell} = \frac{d(v_{k-1}, v_{k+\ell}) - d(v_k, v_{k+\ell})}{d(v_{k-1}, v_k)} \quad (10)$$

Samples	CS	EN	ZH	Total
# Total	2377732	285365	122748	2785845
# $q \geq 0$	1402596	190924	88621	1682141
# $q < 0$	975136	94441	34127	1103704

Table 1: Number of samples for each category in dataset

We compute the average value over several future revisions:

$$q_k = \frac{1}{L} \sum_{\ell=1}^L q_{k|\ell} \quad (11)$$

We set $L = 10$ to compute the final edit quality in data pre-processing. Each edit’s quality is automatically computed and labeled as *damaging* if the quality score $q < 0$, and labeled as *beneficial* if $q \geq 0$.

3.1.3 Competing Approaches

We compare OSEAN with some existing methods:

Average The average approach always outputs the ratio of good edit on the training set as the predict probability.

ORES The Objective Revision Evaluation Service (ORES)[4, 5] is an open-source classifier system developed by researchers at the Wikimedia Foundation.

Interank Interank[12] uses matrix factorization method to learn editor’s ability and page’s difficulty based on the page’s edit history.

StRE StRE(Self Attentive Revision Encoder)[8] is a deep learning based method which combines word level signals as well as character level signals.

ABCNN Attention Based Convolutional Neural Network (ABCNN)[13] integrates attention into CNNs for general sentence pair modeling tasks. We use ABCNN-2 for our edit classification task.

3.1.4 Evaluation

To compare the performance of models, we set up a classification task to predict if an edit is beneficial or not. For

Model	CS	EN	ZH	Total
Average	0.733	0.714	0.814	0.745
Interank	0.448	0.427	0.352	0.436
ORES	0.832	0.852	0.838	0.834
StRE	0.898	0.877	0.884	0.890
ABCNN	0.899	0.912	0.938	0.905
OSEAN	0.946	0.945	0.952	0.947

Table 2: Results on Wikipedia dataset

Model	Ori-Test	On Test Rev-Test	Diff	Ori-Train	On Train Rev-Train	Diff
Average	0.745	0.305	-0.440	0.745	0.270	-0.475
ORES	0.835	0.316	-0.519	0.931	0.286	-0.645
StRE	0.890	0.404	-0.486	0.923	0.345	-0.578
ABCNN	0.905	0.497	-0.408	0.924	0.450	-0.474
OSEAN	0.948	0.755	-0.193	0.993	0.957	-0.036

Table 3: Results for reversed pair experiment. Ori-* denotes the original set, Rev-* denotes the reversed set.

each example, we compute the quality score based on the revision history and assign each example a binary label.

For each particular page, we split the edits on the page randomly into train/validation/test set with ratio 80%/10%/10% and train models. Page-specific models are evaluated and we use the average AUPRC in each category as the final metric which is consistent to previous works[12, 8].

3.2 Basic Experiment (RQ1)

We evaluate OSEAN on the original test set to answer the first question. Table 2 presents the average AUPRC value for each category in original test set. OSEAN has the highest AUPRC and is 4.6% higher than the next-best method, proving the effectiveness of our proposed model.

3.3 Reversed Pair Experiment (RQ2)

In this experiment, we use the same train and validation set as before. For test set, we design two settings:

1. On Test : Trained models are evaluated on original and reversed *test* set.
2. On Train: Trained models are evaluated on original and reversed *train* set.

A reversed dataset is generated by reversing every edit pair and flipping the labels in the original set. According to the definition, an order-sensitive model should have similar performance on original and reversed set. Thus, the difference in AUPRC can be used as a criterion to determine whether the model is order-sensitive. We use average AUPRC of all pages as metric.

Results. Experiment results are reported in Table 3. Interank model is not tested because the reversed sample is anonymous which can not be processed by Interank. Performance of all models drops when classifying reversed pairs. OSEAN has the smallest decline which is 52.7% lower on test and 92.4% lower on train than the next-best method. OSEAN has the smallest performance decline and highest AUPRC on reversed set in both settings, proving that our model can handle reversed edit pairs correctly.

3.4 Training with Augmentation (RQ3)

In this experiment, we use training set with data augmentation to train models. For each example $P = (S, T)$ with label ℓ in training set, we add a reversed example $P' = (T, S)$ with

Figure 3: Results on decline of AUPRC with different proportion of data augmented.

the opposite label ℓ' to the training set. Models are trained on augmented training set and evaluated on both original and reversed test set. We train models with five different cases (i.e. when 0%/25%/50%/75%/100% of reversed training pairs are added). We want to know if data augmentation allows models to learn the information of pair order and empowers models to be order-sensitive.

Results. Performance decline with different rates of data augmentation is reported in Figure 3. As more data is added, the performance gap between the original and reversed test set is also declined. The narrowing of the gap proves that data augmentation can indeed make models more order-sensitive. However, even with 100% data augmentation, the performance gap for all baseline methods is still large, and gap for OSEAN is 37.4% lower than the next-best method.

4. CONCLUSION

In this paper, we present OSEAN, a content-based model for assessing edit quality in wiki-based writing system. Our method utilizes the convolution network to find semantic differences between previous and revised sentences, which can represent an edit. Experimental results on page revision histories from Wikipedia demonstrate that our model can effectively predict new edits' quality. Therefore, we can more accurately determine the quality of student contributions in the project.

ABSTRACT

We present an educational data collecting, mining and analyzing system, EAnalyst, for learners in the K12 period, providing highly intellectual personalized analysis and recommendations for learners. EAnalyst consists of preprocess module, analysis module, dashboard module and recommendation module. To assess target learner's knowledge proficiency better, we extend the current deep knowledge tracing model to achieves the goal of performance predicting. The results on both open dataset and our platform dataset demonstrate the effectiveness of our model run on our platform.

Keywords

E-Learning; Personalized Analysis; Data Mining

1. INTRODUCTION

The rapid development of information technology has helped the "learner-centered" teaching mode attracting more and more attention. With the assistance of big data analysis and artificial intelligence, promoting large-scale data-driven personalized learning analysis has become realistic. EAnalyst is a system whose main goal is to provide intelligent, personalized, and novel assistance to learners.

To meet the increasing needs of personalized learning [1], some existing work focuses on single work or test of a target learner [2] without continuous tracking and analysis of the whole learning process. Chronological data contain hidden patterns that are difficult to detect [3]. There are some attempts on analyzing educational time series data [4], evaluating learners' emotional changes throughout learning process [5], but they didn't consider to make analysis on learners' cognitive level. Some work tried to do cognitive analysis of learning [6], but they didn't combine it with temporal data mining and consider using deep learning techniques.

An intelligent teaching environment helps educators to communicate with learners and be informed of recent states of learners. These technologies make traditional teaching and learning more accurate and intelligent. The quality of education relies more on data analysis than on the experience of educators. Learners are involved in drawing up their learning plans at the

same time. Georgia state university tracks students from arrival to graduation in three years and has made a total of 100,000 active interventions based on the risk alert provided by the system, which has increased the graduation rate of students from 48% to 54% [7]. In Oregon's Beaverton, students' drop-off records, absenteeism records and various demographic information are used to help students adapt to school life better [8].

EAnalyst¹ solves the problem that learners have a hard time figuring out their own knowledge proficiency because of deficient assessment methods and inadequate guidance. Combing domain knowledge with educational data mining and analysis, EAnalyst enables learners to know their knowledge state from the dashboard and provides remedial learning strategy. EAnalyst is an end-to-end system that has been tested on both elementary schools and secondary schools. Thus, the system is designed mainly for learners in the K12 period. The system has been used by part of students of those schools since 2014 and gets notable results in controlled experiments.

2. DATASETS

The data of learners are collected cautiously and critically. Different datasets lead to different outputs. Data of too large or too small granularity can be harmful to the analysis process.

The main component of data collected by EAnalyst ranges from pre-class quiz, post-class quiz, homework, unit-test and term-test. We refer every quiz, homework or test as a collection of series exercises. The former three are mainly about inspecting learners' short-term mastery level on concepts they just learned and the latter two on a larger concept coverage area. Exercises can be both online and offline. Educators use tools provided by the platform to select questions from question bank to form test papers. While offline exercises are commonly used for learners at a young age using the traditional paper test, online exercises are mainly taken on digital devices which can help collecting more information from question answering process such as time spent per question.

3. SYSTEM ARCHITECTURE

We describe EAnalyst architecture illustrated in Figure 1. EAnalyst is composed of preprocess module, analysis module, dashboard module and recommendation module. Preprocess module takes test papers and answer sheets as inputs and outputs structured data; analysis module takes structured data as input, outputs analysis results; dashboard module and recommendation module take analysis results as input then output visualized analysis results and recommendation list.

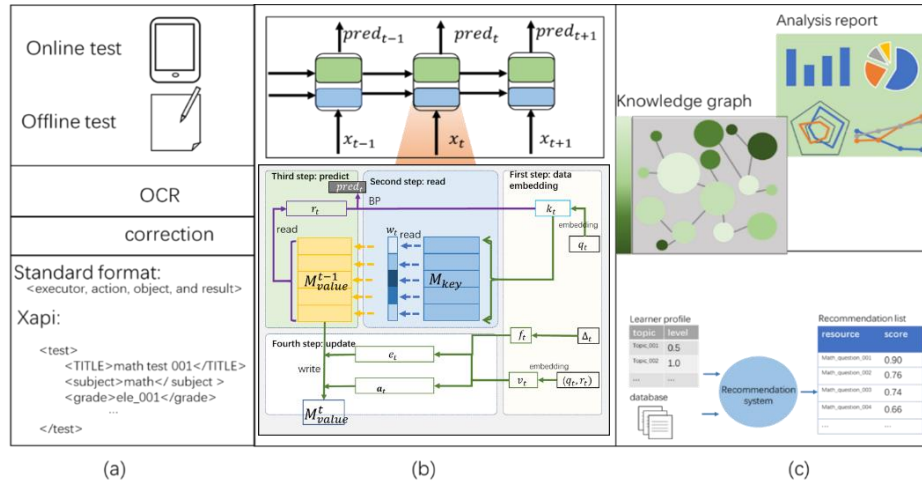

Figure 1. System architecture of EAnalyst: (a) Preprocess module. (b) Analysis module. (c) Dashboard module and recommendation module

3.1 Preprocess Module

Preprocess module uses optical character recognition (OCR) to transfer handwritten answers and correction marks to machine-encoded text. The module applies Transformer [9] which is one of natural language process (NLP) techniques to comprehensively learning question representation so that it can label questions with corresponding knowledge concepts. The response of learners to questions are recorded after being corrected by educators. The module then formalizes those heterogeneous educational data using the Experience API (Xapi), which makes the data readable for machine. Figure 1(a) illustrates EAnalyst's preprocess module.

3.2 Analysis Module

Learners interact with their coursework and generate sequences of learning process records. A sequence consists of multiple interaction record x_0, \dots, x_t . The task of this module can be seen as predicting learner's future performance x_{t+1} . The record x_t at time step t can be represented as $x_t = (q_t, a_t)$ where q_t is a question learner attempts at time step t and $a_t \in \{0, 1\}$ means learner's response (1 means correct and 0 means incorrect). Learning history is then analyzed by knowledge tracing model to reveal learners' learning status. From knowledge tracing prediction, educators can identify specific areas where learners need extra help. Educators can also analyze the data of the whole class to see their learning habit and adjust courses according to the feedback. Educators can even compare this information with that from other grades to determine which teaching methods are most effective.

The datasets that are used by knowledge tracing model are collected during the 2017-2019 school years. The datasets we conducted experiments on is on math subject, which has covered 652752 practice attempts of 3962 students on 4784 distinct questions. We filter learners who has fewer than three exercises to guarantee the reliability of knowledge tracing results since sequences that only contain one or two exercises barely contribute to tracing knowledge state of learners. We summarize some statistical features of two datasets in Table 1 and EAnalyst dataset distribution in Figure 2. For EAnalyst dataset, the average number of records per learner is 165. For EAnalyst dataset each learner interacts with more distinct questions than that in open dataset, which makes EAnalyst dataset more sparse.

Deep learning has made a huge success in tasks like image recognition, natural language processing (NLP), voice recognition and etc. Tasks which are good at handling sequential data use model like Long Short-Term Memory (LSTM) networks [10], a type of Recurrent Neural Networks (RNN), and get good results. Compared with models based on statistical graph like Bayesian Knowledge Tracing [11] and models based on matrix decomposition like Knowledge Proficiency Tracing [12], models based on deep learning, called Deep Knowledge Tracing (DKT) [13] are more flexible, which can be combined with effective mechanics so that they can make use of other information like content of questions and domain knowledge. DKT uses LSTM and its variation to cover previous learning records in a long time period to detect learners' knowledge state and memorize it in hidden vectors. This method has been combined with the attention mechanism to evaluate similarity among different question contents to improve prediction accuracy [14].

Table 1. Statistics of two datasets

Dataset Name	EAnalyst Dataset		Assistment2009 Dataset
Attribute of Dataset	Original	Pruned	Original
records	657573	652752	525534
learners	4285	3962	15931
questions	4788	4784	124

Figure 2. Distribution of EAnalyst Dataset on math subject.

Models like memory network [15] which has worked well in NLP field has also performed well at learning correlation between different questions. Model [16] using static key memory matrix to store question-concept relationships and dynamic value memory matrix to store and update concept-learner state relationships. This model performs well at knowledge tracing. We inherit the advantage of two memory matrices and apply convolution neural networks with some additional calculation to the reading process in the third step to reduce information loss in reading memory matrix process. We also consider the forgetting behavior of learners and add time interval of adjacent exercises to the updating step so that the model can simulate forgetting behavior. At first step, input data will be embedded. At second step, a question q_t is used to retrieve related concept position w_t in key matrix. At third step, position w_t is used in value matrix to query corresponding concept state. Finally, the concept state is used to predict learner's future performance on q_t . At fourth step, only related concept state will be updated in value matrix. The overall structure is illustrated in Figure 1(b).

We compare the prediction accuracy on both our dataset and public benchmark dataset—Assistment2009 [17]. Assistment is an online platform which teaches and assesses learners in elementary school mathematics. It is also the largest available public knowledge tracing dataset. We use Area Under a ROC Curve (AUC) to measure performance of the traditional model and deep learning model. AUC value ranges from 0.5 to 1 where the former value indicates the prediction result by random guessing and the latter represent precise prediction.

We set all sequences to be length of 150 and use -1 to pad short sequences to the expected length. The parameters are initialized randomly using Gaussian distribution. We set batch size for Assistment2009 dataset to 32 and that for EAnalyst dataset to 16 due to limitation of gpu memory. For momentum, it is set to be 0.9 and for norm clipping threshold to be 50.

The performance of different models is listed in in Table 2. The comparison results lead to findings that EAnalyst model can produce relative good result on Assistment2009 and better prediction results on EAnalyst dataset considering EAnalyst dataset are much sparser than Assistment2009. And Our model does not come into the problem of overfitting due to its complexity compared to DKT's LSTM network.

Table 2. Performance of different models on two datasets – EAnalyst dataset and Assistment2009 dataset (AUC)

Model	EAnalyst Dataset	Assistment2009 Dataset
Bayesian Knowledge Tracing	0.69	0.73
Variant of Bayesian Knowledge Tracing	0.75	0.82
Deep Knowledge Tracing on EAnalyst platform	0.85	0.86

3.3 Dashboard Module

Dashboard module is a visualization tool for learners displaying results of analysis on knowledge graph, which is illustrated in Figure 1(c) upper part. Educators and experts in education field construct the knowledge graph manually according to textbooks and their experience. Knowledge graph constructs a network of knowledge concepts, which are connected by lines with relevant knowledge concepts. The size of each concept is related to its

importance. The importance level is valued by corresponding syllabus. The more important a concept is, the bigger is a node. Color depth of a node indicate how a learner mastery a concept node. Each subject includes multiple knowledge graphs divided by school year while some concepts can appear in one or more graphs. Knowledge graph is a precondition of accurate analysis of learners' overall cognitive levels, knowledge state and appropriate learning path recommendation. A learner and his or her educator can locate weak spots easily. And having a big picture of one's knowledge state helps the learner to carry out the following remedial activities.

Analysis report giving a more detailed description of a learner's learning report. History of exercises will be evaluated in a statistical point of view. Different types of charts such as histogram, pie chart, radar chart and line chart. These charts can well represent changes in learning indicator of learners over time, break out learners of a class by percentage of accuracy they have got, show distribution of a learner's overall quality and give a rough comparison between the learner and the average level of his or her class and grade. Figure 3 gives a partial screenshot of a learner's dashboard in elementary school mathematics.

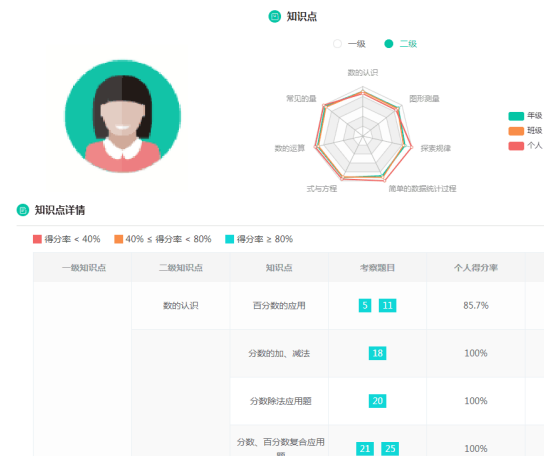

Figure 3. concepts mastery level in a radar chart and statistical report

Analysis report giving a more detailed description of a learner's learning report. History of exercises will be evaluated in a statistical point of view. Histogram represents change in learning indicator like accuracy over time. Pie chart breaks out learners of a class by percentage of accuracy they have got. Radar chart shows distribution of a learner's overall quality. Line chart gives a rough comparison between the learner and the average level of his or her class and grade.

Dashboard contains statistical reports generated from analysis module and knowledge graph presenting learner's knowledge proficiency. The report displays learner's test results, test analysis. The circle in the graph represents separate entities. The importance of the entity is distinguished by size, and the depth of color indicates the learners' mastery level of each entity. The line between two circles displays relation existing between two corresponding entities. Dashboard works as an effective tool to promote learners to define and achieve goals.

3.4 Recommendation Module

Recommendation module mines learner features and course features, uses learners' rating of learning materials as supervised labels to filter recommendation materials like reading material, exercises, notes and outstanding answers from learning partners. We form a learner-course feature vector matrix by combining learners' behavior data with attributes data from learners and courses. This module first uses extraction capabilities of deep belief networks (DBN) to collect features from learner-course matrix to represent learners' preference. This feature extraction part is composed of bottom-up unsupervised pretraining using layers of restricted Boltzmann machine (RBM) and top-down supervised parameter fine-tuning using Backpropagation (BP) in the last level of the DBN. The trained DBNs from unsupervised part and corresponding rating score labels are used as inputs to the BP supervised part [18]. Then the recommendation model can be used to rating learning materials with scores. Materials with scores are ranked and those with higher scores are recommended to learners. The process is illustrated in Figure 1(c) lower part. This recommendation list will be updated dynamically according to newly generated learning tracks to match learners' changing needs.

4. CONCLUSION

We present EAnalyst, a learner's assistant developed by applying deep learning techniques for large-scale educational data mining and analysis. The system takes temporal data analysis aligned with knowledge graph, presents learners with multidimensional analytical reports, and recommending learning paths by offering relative learning materials. In the future, we intend to solve the "cold start" problem of learners' performance evaluation process and improve the analysis model by adding question content so that the deep relation between questions and learners' state can be exploited.

ABSTRACT

How do people talk about math? What point are we making when we contrast math with other topics? In studies of school performance, attitudes, and stereotypical beliefs, math is most frequently compared to language abilities and occasionally artistic qualities. Most studies about these topics administer assessments and closed-form surveys to make sense of how math ability or beliefs are different from similar constructs in other educational domains. In an analysis of Google search terms using Google Trends, “math” occurs in search queries far more frequently than “language” or “art” and —unlike searches about the other topics—the prevalence of “math”-related searches shifts in conjunction with the academic year. This project’s goals are to (1) sample from diverse naturalistic text-based datasets to expose how math is referred to in non-experimental settings and (2) identify similarities and differences between math and the domains most frequently used as contrasts. We perform computational analyses on text derived from naturalistic sources written across a variety of different registers, from a journalistic source (NY Times) and a social media website (Twitter) to referential sources containing basic definitions (Merriam-Webster) and more informal descriptions (Urban Dictionary). We see that, across data sources, queries related to “math” refer more frequently to education-related themes and incorporate more disparaging terminology compared to content related to “language” or “art.” This project is a first step in demonstrating that this methodology can aid in exploring more realistic discourse surrounding math and domains of comparison. This can inform and empower future researchers and practitioners interested in changing the discussion around math.

Keywords

math, language, art, naturalistic data, big data, NLP

Rachel Jansen and Ruthe Foushee "How we talk about math: Leveraging naturalistic datasets to define the discourse of math in contrast to other domains" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 624 - 628

Math is frequently discussed in a derogatory way: “Everybody hates math” is a major trope in popular media, with hundreds of instances across television sitcoms, comics, and movies.¹ In addition, when researchers investigate attitudes about math, they tend to focus their efforts on the study of math *anxiety* [2, 6], as opposed to positive feelings. These ways of portraying math, both in the media and in research and education appear unique to math. When researchers measure stereotypical beliefs [4] or attitudes about another subject [8], they are typically included as a contrast to math.

In public discourse, this differential treatment of math compared to other domains is perpetuated by *neuromyths*, or false ideas about the brain, such as the idea that “some of us are ‘left-brained’ and some are ‘right-brained’ and this helps explain differences in how we learn” [12]. Implying a natural contrast between math ability and art or language ability does a disservice to students, current and former: it encourages the belief that if we are “good” at one thing, we cannot be “good” at another. Beliefs about innate brilliance further amplify the folk distinction between math and art. Math is perceived as requiring the most brilliance out of any STEM discipline, and significantly more than all art and language-related fields, including English Literature, Art History, Linguistics, and Music Composition [10]. Such essentialist beliefs about domain-specific ability are bolstered by parallel sex disparities, with more “brilliant” fields like math including significantly fewer women.

In this project, we capitalized on naturally occurring data where people discuss math, and compare parallel discourse about other domains. We specifically analyze communications related to language and art, as these are frequently compared to math. We detail our rationale for each comparison domain in the next section.

0.1 Comparison domains

In research contexts, language very frequently serves as a comparison domain for math. Math is compared to language—and most often reading and writing skills—in research on ability [7], stereotyped beliefs [4], theories of intelligence [8]. [14] contrasts STEM performance (math and science) with non-STEM (language, humanities, and social science) and

¹<https://tvtropes.org/pmwiki/pmwiki.php/Quotes/EverybodyHatesMathematics>

finds no actual performance difference nor evidence for gender differences in variability in academic grades.

On the other hand, art is much less studied in relation to math, in part because it is far more difficult to design art assessments than math or language assessments, and judging art ability is perceived as subjective. Some work has contrasted creative ability in math and art [9] and explored gender differences in stereotypical beliefs across the two areas [16]. More frequently, when conducting research on a task that involves some artistic expression in research about math ability, the idea of “art” goes unmentioned, as with drawing [5] or any study of spatial ability [1].

In studies comparing math ability or perceptions to parallel constructs in another domain, no justification is given for the choice of alternative domain. It may seem obvious to us that reading ability is the most direct contrast to math ability, but this is precisely what we are interested in accessing in this project. The assumptions about concepts and distinctions among them present themselves in our communications. Therefore, investigating naturally occurring data may provide us with the justification we need for domain comparison choices across different contexts. We assert that though art is only sporadically studied in relation to math, there are many reasons why it may serve researchers as an appropriate foil. For example, math is a required course throughout schooling and necessary for attending college, while under budget shortages, art classes are the first to be cut from curricula. However, mathematicians regularly enjoy drawing comparisons between artistic and mathematical abilities [11, 3]. This perceived distinction in the relative utility of math and art, paired with experts’ regular likening of the two suggests an interesting avenue of future work.

0.2 Measuring math talk

Human attitudes are typically explored via closed-form surveys. But sampling bias as well as the wording of the questions can impact responses. We propose using naturally occurring datasets to supplement existing research about math attitudes and as a guide for developing new theories and experimental paradigms [15].

The goals of this paper are 1) to source data from non-experimental contexts to examine naturalistic discourse surrounding math and its comparison domains and 2) to identify how math is discussed that may be distinct from related domains in similar contexts. We hope to make an empirical case for comparing math to specific domains: why and when do we measure math against language or art, and what might be the appropriate choice based on how people represent these domains? We locate several sources of communication spanning a range of genres (e.g., journalistic, social media, and references), and registers (from more formal to informal writing styles).

1. METHODS

We identified a variety of online sources with freely accessible APIs (Application Programming Interfaces). We first used the Google Trends and English Lexicon Project as measures of frequency of term usage. Next we collected a selection of articles from the New York Times, tweets from Twitter, and definitions from the Merriam-Webster dictionary and

Urban Dictionary that related to the search terms “math,” “language,” and “art.”

1.1 Data sources

Though Google does not provide access to search history data, the company built an online interface, Google Trends,² for observing both fluctuations of searches for specific keywords or topics over time and across locations [17]. We focused our observations exclusively on the US. As another overview of frequency of specific terms, we used the English Lexicon Project (ELP).³ These sources provide a very general sense of how these topics are thought about differently. We next explore actual word usage in multiple other sources, namely the New York Times, Twitter, and two different online references (Merriam-Webster and Urban Dictionary). Two of these may be seen as relatively objective (Times and Merriam-Webster), though a computational analysis of word usage will show whether this is truly the case.

We used the “Article Search API” from the New York Times (NYT)⁴ to collect all hits that include the terms “math,” “language,” and “art.” The NYT API provides the headline, keywords, date, word count, and lead paragraph for all articles that come up for a specific search term. The NYT Article Search API yielded 441,773 searches for “math”, 367,707 for “language” and 1,276,036 for “art.” We sample approximately 2,000 results for each search term.

Twitter is the only social media company that offers easy access to their data, in part because posts are all expected to be public anyway.⁵ In order to align results with the data we obtained from the NY Times, we used the twitter package for Python⁶ to load 2,000 tweets per search term.

Merriam-Webster additionally offers easy access to their definitions.⁷ Preliminary data mining returned just the definitions for each term of interest, but it is meaningful that “math” has three definitions, while “language” and “art” each have ten. From Urban Dictionary, we downloaded all existing results for each term, which was 856 for math, 262 for language, and 876 for art (see Table 1 for total documents used in analyses for each term and each data source).

1.2 Text Analyses

With each data source, we created Naïve Bayes classifiers to contrast word usage for documents about math, language, and art.⁸ Prior to text analyses, we ran a series of standard text pre-processing techniques: a) removing stopwords b) removing punctuation and c) reducing words to their roots (stemming and lemmatizing). To test the accuracy of each classifier, we shuffle the data and separate it into a training set consisting of 80% of the data and a test set comprising the remaining 20%. We train the classifier on the training

⁸We employ the NaiveBayesClassifier function from Python’s Natural Language Toolkit (nltk version 3.2.2) package <https://www.nltk.org/>

set, then report the classifier’s accuracy predicting responses on the test set, alongside a subset of informative features (words that are more common for one specific subgroup).

2. RESULTS

2.1 Google and ELP

From Fig 1, created from data generated in Google Trends to compare searches pertaining to the topics “math,” “language,” and “art,”⁹ it is clear that, compared to the other topics, math is generally searched for at a higher rate, though takes steep dives in the summer months when school is no longer in session. This suggests that the term “math” is much more associated with education than other topics, and idea we explore in more detail in the other data sources. Contrary to Google search results, an analysis of term frequency in the English Lexicon Project reveals “math” to be significantly lower frequency (18,404) than terms relating to “language” (97,874) or “art” (62,513). According to this source, “math,” “language” and “art” are estimated to be acquired at similar ages (5.56, 6.79, and 6.21 years, respectively), but “language” is rated as notably more abstract (that is, less concrete: language: 2.35, math: 3.15, art: 4.17).

	MATH	LANGUAGE	ART	TOTAL
NY TIMES	1,541	1,946	1,835	5,322
TWITTER	2,000	2,000	2,000	6,000
M. WEBSTER	3	10	10	23
URBAN DICT.	856	262	876	1,994

Table 1: Number of documents for each corpus.

2.2 Journalistic source

We excluded a set of “math” searches to ensure that the results would not be overly skewed. Specifically, 270 hits contained a daily math challenge and the lead paragraph began with “Test your math skills with today’s question” and an additional 40 started with “Our weekly math problems are written by teachers at Math for America.” For “art,” we excluded 157 whose lead paragraphs began with “Our guide to new art shows and some that will be closing soon.” There did not appear to be anything so consistent for searches relate to “language.” Search results with blank lead paragraphs (159 math; 18 art; 64 language) were excluded from our training data. First, we analyzed the distribution of keywords. Of the 1541 math queries, 323 contained “school” (21%) compared to 81 of 1946 language queries (4%) and 14 of the 1835 art queries (0.8%). There was a similar pattern for the keyword “test,” included in 149 math queries, compared to 6 and 1 for language and art, respectively.

We next looked at the text from each lead paragraph. We used all three sets of nonempty lead paragraphs for each topic to construct the classifier which included a total of 5,322 texts (1541 math; 1946 language; 1835 art). After removing all terms with roots “math,” “language,” or “art,” the classifier achieved 70% accuracy on the test set. The most informative features for math included “test,” “score,” “grader,” “improv,” “educ,” “competit,” and “teacher” (e.g., “Growing up, I thought math class was something to be

⁹<https://trends.google.com/trends/explore?date=all&geo=US&q=%2Fm%2F04rjg,%2Fm%2F04g7d,%2Fm%2F0jjw>

endured, not enjoyed. I disliked memorizing formulas and taking tests, all for the dull goal of getting a good grade”). The most predictive terms for an art-related hit contained “galleri,” “sculptur,” “paint,” and “noteworthy.” For language-related queries, “speak,” “translat,” “dictionari,” and “writer” were most informative. Though there are no apparent emotive terms, math arises much more frequently in documents related to school than does art or language in this context.

2.3 Social media

The average word count for tweets corresponding to each term was approximately equal (18 for math, 19 for language, and 18 for art), likely due to platform word count restrictions. In our classifier (accuracy: 62%), informative features for tweets about math included words very similar to those from the NYT, such as “test,” “fail,” “wrong,” “class,” and “science.” For language, we saw “tiktok,” “english,” “speak,” “video,” and “utter.” The set of most informative features for art contained “draw,” “style,” “anim,” “design,” and “cute.” Here, we see many domain-specific similarities to the NYT data, but with the addition of terms conveying negative emotions related to math, such as “wrong,” “fail,” and “hard,” which might speak to the greater subjectivity of the text source. The language- and art-related searches also appear to encompass more popular culture references. There was an interesting pattern of math being more ubiquitous in tweets relating to current events such as the election: ‘berni,’ ‘vote,’ and ‘warren’ (e.g., “Math says that Warren has a path”) and the coronavirus outbreak: “million,” (e.g., “It is simple math. The flu infects millions a year”).

2.4 Reference materials

The Merriam-Webster dictionary produced few results, but the primary definitions themselves serve as a baseline set of relevant objective terms. Mathematics is defined as “the science of numbers and their operations,” language as “the words, their pronunciation, and the methods of combining them used and understood by a community,” and art as “skill acquired by experience, study, or observation.” By their very definitions, math is a science (rather than an art) and art is not said to require innate ability.

The Urban Dictionary API yielded 856 definitions of “math,” 262 of “language,” and 876 of “art.” The mean length of the math definitions was 36 words, 49 for language, and 58 for art (similar to the NYT results). Because this corpus was not evenly distributed across topics, we ran separate classifiers between each pair of topics, rather than over all 1,994 total definitions. For the math/art classifier ($n = 1732$), accuracy on the test set was 79% and the most informative words for math definitions were almost all negative: “abus,” “number,” “mental,” “stress,” “tortur,” and “bore.” For art on the other hand, informative features included “style,” “emot,” “draw,” “amaz,” “visual,” and “color.” The classifier comparing math to language yielded an accuracy of 85%¹⁰ and primarily identified words that were informative of the language texts, as they represented a smaller proportion of our dataset. These included “speak,” “talk,” and “special,” while terms more indicative of a math entry were “abuse,” “mental,” “human,” and “bore.”

¹⁰Chance would be 77% because 77% of definitions are math ones.

Figure 1: Google trends patterns of searching for the topics “mathematics,” “language,” and “art.”

Finally, the classifier comparing art and language arrived at an accuracy of 85% and words from art-specific definitions included “music,” “best,” and “style,” while definitions of language included terms “sign,” “french,” “wrong,” and “number,” which potentially likens math to language more than to art. Analyses of the example sentences included for each definition from Urban Dictionary produced comparable results, with notably more derogatory and profane terminology used to describe math than the comparison domains.

3. DISCUSSION

In a preliminary analysis of naturally occurring data sources, we have observed that math is more frequently written about and discussed in relation to education compared to language and art. In contexts where valenced language use is common (Twitter and Urban Dictionary), math is discussed using notably more unflattering terminology. Each data source we explored yielded different frequencies at which the three chosen topics were mentioned. Our Google Trends analysis revealed that math is searched for more frequently than language or art. However, though the NYT provided fewer “language” articles than “math” ones, there were more than double the number of hits related to “art” (owing to “arts and leisure” having its own section in the newspaper). In the references, “math” had fewer entries in Merriam-Webster compared to language and to art, but in Urban Dictionary, there were a comparable number of entries for “math” and “art,” and this was more than triple the number of “language” entries.¹¹ Based solely on these simple search counts, we can identify important differences in how these topics are thought about: “math” appears to be defined more narrowly than the other domains (based on Merriam-Webster definition counts and shorter text lengths in the NYT and Urban Dictionary data) while emotions surrounding “math” and “art” are stronger than for “language” (based on the relative number of Urban Dictionary results). “Math” is also much more associated with education, a claim supported by the keywords from the NYT, our classifiers’ informative fea-

tures from the NYT, Twitter, and Urban Dictionary data, and from the cyclical nature of Google searches for “math.”

4. FUTURE DIRECTIONS

This set of analyses only scratches the surface of what is possible with this methodology. We have many plans for further research, namely to conduct additional analyses on the data presented here, gather more data through clouds of novel search terms, and explore other naturally occurring data sources. First, to expand the findings from the data already gathered, we will conduct text-based sentiment analyses to search for systematic differences in overall valence associated with each term, and perform topic modeling over each set of documents. Second, “language” and “art” are only two of many possible domains to compare to math, alternatives to which we will pursue in future work. We aim to use the work done so far to refine our terms to determine what comparisons are more useful for different contexts. Finally, we intend to search deeper and with more specific intentions within the sources we have scrutinized thus far as well as among other potential sources of data.

5. CONCLUSION

Using large-scale datasets of naturally occurring text, this work presents a preliminary exploration of how math is discussed, compared to its most frequent comparison domains. Our data confirm that math is generally spoken about in a manner that is both more limited (e.g., to educational contexts) and more negatively valenced. Previous work has shown that familiarity with an idea increases belief in that idea [18], which means that the restricted and unflattering ways in which we generally discuss math may progressively degrade public opinion about the topic. If—through the media and other sources—speakers continue to hear (or read) about math as a narrowly defined concept associated with negative emotions, this perception will continue to thrive, and be unwittingly transmitted to future generations [13]. Thus, this work also serves as a plea to limit unnecessary disparaging reference to math in mass communication.

¹¹We were not able to acquire total hit numbers from Twitter.

Predicting Student Dropout by Mining Advisor Notes

J.D Jayaraman

New Jersey City University and Teachers College, Columbia University

jjayaraman@njcu.edu

ABSTRACT

More Americans are attending college than ever before but almost half of them do not complete college. Thus, early detection of students at risk of dropping out of college is of paramount importance. This study describes a novel attempt at using notes made by student advisors to predict student dropout. We use a Natural Language Processing (NLP) technique called sentiment analysis to analyze unstructured textual data to extract the positive or negative sentiment contained in the advisor's notes. We then use the sentiment extracted from the notes as features to train a random forest model to predict student dropout. We achieve 73% accuracy in predicting student dropout. Thus, our study demonstrates the value of unstructured data held in institutional databases for identifying at-risk students.

1. INTRODUCTION

Student retention is a major challenge at American universities with the average 6 year graduation rate hovering around 59% [12]. Graduation rates vary with institutional selectivity [19]; the situation being particularly grave at institutions with open admission policies where the 6 year average graduation rate is a meager 32% [12]. Low retention rates not only impact the financial well-being of individuals but the economy as a whole, since it is a well-established fact that income level rises with a college degree. Median income levels for young adults with a bachelor's degree are 64% higher than those with only a high school diploma [12]. Low retention rates also adversely affect the reputation of the educational institution and could lead to potential loss of funding and inability to compete for quality students. Thus, improving student retention is of paramount importance at institutions of higher education.

A critical factor in increasing student retention is the ability to accurately identify at-risk students, so that relevant interventions can be provided. Much of the prior research has been devoted to modeling the factors that impact student retention using traditional statistical methods. But, machine learning and data mining techniques have started becoming actively employed in student retention research in the recent past. Most research articles, though, have been focused on using structured data, such as GPA, SAT scores etc., that are readily available in institutional databases. To

the best of our knowledge, as of this writing, there is no literature that tries to use unstructured data (e.g. free form text, images etc.) in predicting student dropout. Roughly 80% of the data generated in the world today is unstructured. Large amounts of unstructured data are generated by universities and colleges. Examples include advisor notes, discussion forum postings, online chats, emails etc. This is a treasure trove of information that has not been adequately exploited to help predict student dropout.

This paper describes a novel approach to predicting college student dropout using the information contained in free form notes recorded by student advisors on a student advising platform (e.g. EAB). We use Natural Language Processing (NLP) techniques to unearth the information contained in these advisor notes and use it to predict student dropout. To the best of the author's knowledge this study is one of the first to employ NLP techniques to predict student dropout. Thus, our study contributes to the literature by introducing an additional novel approach to predicting student dropout by using NLP techniques to analyze unstructured textual data in the form of advisor notes.

2. LITERATURE REVIEW

Research on student attrition has traditionally been based on surveying student cohorts and following them to assess dropout. These surveys contributed to the building of theoretical models of student retention, the most famous of them being the Tinto model [16]. Survey based research have been criticized for being too specific to an institution and hence not generalizable [1]. Also, these large scale surveys are not cost-effective to conduct. An alternative to survey based research is to use the data that most higher education institutions routinely collect about their students. This type of research based on institutional databases has been shown to be comparable to survey based research [2].

Prior research has also been mostly focused on identifying various factors that impact student dropout. Tinto [17] highlights academic difficulty, adjustment problems, lack of clear academic goals, lack of commitment, inability to integrate with the college community, uncertainty, incongruence and isolation as factors involved in student dropout. Tinto's theory of student integration posits that past and current academic success are crucial factors in determining student attrition and many studies have found high school GPA and SAT scores to have a strong effect on student retention [13]. Declaration of major and number of credit hours taken during the first semester have been used as proxies for institutional and goal commitment and have been found to be significant predictors of student attrition [1]. There have been many studies that have investigated the effect of financial aid on student retention [8, 9, 14]. These studies found that the type of financial aid that the student received had an impact on student retention.

Students receiving aid based on academic achievement had higher retention rates, while student loans had a negative effect on retention. Also, if students lost a scholarship or grant due to poor grades, it had a negative impact on retention. Thus, as evidenced above, almost all the studies have focused on factors that are part

J.D Jayaraman "Predicting Student Dropout by Mining Advisor Notes" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 629 - 632

of structured data collected by educational institutions. Factors such as emotions and sentiments that are embedded in unstructured data, have not been considered much in the literature.

Research on using machine learning techniques to predict student attrition is still in its infancy. Delen [6] used a dataset consisting of 39 variables such as SAT score, high school GPA, hours registered, hours earned etc. and several machine learning methods such as support vector machines and neural networks to model freshmen student attrition and found that support vector machines performed best, reaching a prediction accuracy close to 80%. Thammasiri, Delen, Meesad and Kasap [15] used data and techniques similar to Delen [6] to predict whether students would enroll for the second term. Lauria, Baron, Devireddy, Sundararaju, and Jayaprakash [10] used demographic and course related data to show that support vector machines performed better than decision trees at predicting at-risk students. Thus, almost all the research on student dropout prediction using machine learning and statistical techniques has focused on using structured data.

While there is not much literature using NLP techniques and unstructured data in predicting college student dropout, there is some recent literature in the related area of predicting student completion in Massive Open Online Courses (MOOCs). The most common NLP technique employed in these studies is sentiment analysis, which examines language in discussion forums and assignments to detect positive or negative emotion words and words that convey motivation, engagement etc. Wen, Yang, and Rose [18] examined students' opinion towards the course based on a sentiment analysis of discussion forum posts and used these opinions to predict course completion. Wen et al. [18] found that students who used words related to motivation were more likely to complete the course. Crossley, Paquette, Dascalu, McNamara, and Baker [4] used NLP techniques on MOOC forum posts and found that lexical sophistication, writing quality were predictive of student completion. Our study uses similar approaches to the literature described above but applies sentiment analysis to free form notes entered into an advisement system by the student's advisor, in order to predict student dropout.

3. METHODOLOGY

3.1 Data

The data consists of 19,562 notes entered over a period of four years (2015 - 2018) for 7343 undergraduate students at an urban university in the North Eastern United States which caters to a largely minority population. These notes are made by the student's advisor after each meeting with the student and are keyed into the student advisement system. These notes are free form and do not have any structure to them. Students typically meet with the advisor multiple times a semester to discuss enrollment, progress and any other issues. The notes the advisor makes documents the meeting in a reasonable amount of detail. Thus the notes are rich with information on any issues and difficulties students might be facing not only with respect to their academics but also with respect to their social and family life. We also compiled data on whether a student dropped out or not (a binary indicator variable). A student was considered to have dropped out if he or she did not enroll in any semester following the last semester of enrollment. Based on this definition we constructed a binary indicator variable to indicate whether a student has dropped out or not.

3.2 Analysis

3.2.1 Sentiment Analysis

Sentiment analysis is a NLP technique that attempts to categorize the emotions and sentiments in a block of text. Most sentiment analysis tools will categorize the sentiment as positive, negative or neutral and also provide indexes for affective states such as anger, sadness, happiness, etc. Sentiment analysis has been widely used to mine emotions from social media posts and has been effective in identifying depression, anxiety and other emotions [15].

There are two main approaches to extracting sentiment from text. The lexicon based approach uses a dictionary of words annotated with their sentiment polarities, while the text classification approach involves building classifiers from labelled instances of texts. Lexicon based approaches work well when there is insufficient human classified data or when human classification is time consuming and expensive. We use the lexicon based approach in this study as it would be very time consuming to hand classify the sentiment in the advisor notes to create a large enough training dataset. There are several sentiment lexicons available. We use a popular lexicon called the Bing lexicon [11] which consists of 6800 words, 2000 of which are positive and 4800 are negative. We also constructed a custom lexicon of 100 sentiment words relevant to the student retention domain and combined it with the Bing sentiment lexicon.

We preprocessed the data by removing stop words, punctuations, numbers, white spaces and other words such as will, student, etc. that would not be pertinent to conveying sentiment. The sentiment analysis was done on the preprocessed data. The output of the sentiment analysis is a list of words in each note tagged with a sentiment (positive or negative).

3.2.2 Imbalance

Data is said to be imbalanced if the number of instances in one class significantly outnumbers the number of instances in other classes. Since the number of dropouts is much smaller when compared to the number that don't dropout, student retention data sets are typically imbalanced. If the data is imbalanced the standard classifiers have a bias towards the larger majority class. One approach to correcting this imbalance is to preprocess the data in order to balance it out and then build the model. This approach uses various techniques to either oversample the minority class or undersample the majority class. Random oversampling attempts to balance the data by randomly sampling from the minority class and adding them to the training data set while random undersampling attempts to balance the data by removing data instances from the majority class. Undersampling has been shown to perform better than oversampling in some cases [7]. Synthetic Minority Oversampling Technique (SMOTE) is a popular and robust technique that uses a combination of oversampling the minority class and undersampling the majority class which results in better classifier performance than just oversampling or undersampling [3]. Our study uses SMOTE to correct the imbalance.

3.2.3 Classification

From the output of the sentiment analysis we computed the number of positive sentiment words and number of negative sentiment words in a note. We then computed the ratio of the number of positive sentiment words to the total number of words in a note. This ratio and the number of positive sentiment words were used as

approach and hand classify the advisor notes to create a training dataset to predict dropout. It would be interesting to compare this type of approach and the lexicon based approach to determine if the expense of hand curating a training dataset is worth it. Further, we could combine the features extracted from the advisor notes with other traditional features such as GPA, SAT scores etc. to improve our prediction accuracy.

6. CONCLUSION

Unstructured data captured in various databases across the educational institution, including in online learning platforms (e.g. Blackboard), are a treasure trove of information that has not been adequately exploited to help the student in improving performance and avoiding dropout. Our study was an attempt at utilizing a small part of this unstructured data to help in the early identification of at-risk students. The fairly high level of prediction accuracy obtained in our study, even without much performance tuning, demonstrates the value of unstructured textual data in institutional databases for detecting at-risk students by predicting student dropout.

Future research should focus on unlocking the potential of unstructured data in institutional databases in helping the student. Other forms of unstructured data such as images, videos, audio clips, illustrations etc. that are created by students for different courses should also be used to extract information that could help provide early intervention and improve student retention.

ABSTRACT

The assessment of students based on their tasks is important in Education, and many advanced methods are applied to the field to solve this problem. Many recent neural network approaches involve heavy modeling of the contents and students. However, it is shown that using pairwise comparisons without the direct usage of instance features can show better assessments in the aspect of consistency, and speed. These ideas have been examined in various perspectives since Thurstone proposed the idea of Comparative Judgement(CJ). Whereas CJ requires direct comparisons of instances to obtain the final fit of the label, we give a generalization by proposing a label prediction model which uses the multi-dimensional features of pairwise comparisons. By reducing the cost in label inference, an Education service can provide visualizations of multi-dimensional skill levels for better meta-cognition of the users. Experimental results on the open dataset *EdNet KT1* show that our method gives higher accuracy even without using the actual responses for the model input.

1. INTRODUCTION

In the development of Intelligent Tutoring Systems (ITS), student assessment from their tasks and interactions is a central problem. It is shown in general education scope, that student assessment is highly correlated with the improvement of motivation, engagement, and achievement of the students. Especially in ITS, the decisions of tutoring strategies in many cases rely on algorithmic assessments of student performances. Instances of tutoring decisions include providing educational feedback or adjusting the provided contents to the students in the system. For interactive education systems, real-time computation of assessment is required, and various methods are implemented to settle the

computation time problem.

Methods for student assessment have been studied in various aspects, including well established fields such as Item Response Theory(IRT), Cognitive Diagnosis Model, and Knowledge Tracing. In real-world systems, many assessment methods are based on domain expert knowledge, such as Knowledge Graphs, tagging of contents, and expert designed rule based models (such as the Rasch model in IRT). Recently, data-driven methods with less dependency on domain expert knowledge are also widely applied in ITS. Collaborative Filtering approaches such as Matrix Factorization, or Neural Collaborative Filtering are applied to embed users and items for tasks such as student response prediction, and content recommendation. There are also fully data-driven deep neural networks with no domain expert dependencies that are capable of modeling, prediction, assessment, and recommendation problems in Education such as Deep Knowledge Tracing. These methods not only show high accuracy for the target tasks, but are also easier to apply to new domains since they are domain independent.

However, many existing data-driven methods, including neural network models, require large volumes of training data and also require high costs on inference computations for achieving high performance. Methods based on domain experts can have less complexity, making their operating costs low, but developing such methods often requires a high cost on domain experts. This cost problem can be a barrier on providing e-learning services to people in underdeveloped countries, which also results in digital inequality. [8]

In this paper, we propose two assessment models based on pairwise comparisons to solve the assessment cost problem on data, and inference computation aspect. The key concept of the proposed method is to design a multidimensional generalization of Comparative Judgement(CJ). Instead of using each response data for assessment as in many supervised learning models, we only use pairwise comparisons of user responses. This model can be trained using significantly less label data compared to existing data-driven methods. Also, pairwise comparison data can be gathered within the ITS itself without additional cost. This reduces the cost to gather labeled data, and since the proposed model has less complexity, the computation cost for assessment is also reduced.

We evaluate the proposed methods that use pairwise comparison data by comparing the results with other baseline

Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 633 - 637

models that directly use response data for predictions.

2. RELATED WORKS

2.1 Student Assessment

Various data-driven student assessment methods have been studied by researchers of ITS, where most are based on three main approaches: knowledge tracing models, collaborative filtering based models, and domain knowledge based models. Knowledge Tracing(KT) is used as a term on various assessment methods to model users by their interactions within a tutoring system [3]. Yudelson, et al. [26] suggested a Bayesian model that estimates the student performance by response correctness data. Piech, et al.[13] applied deep neural networks to KT. Some approaches [1] involve the modeling of contents and students, using pre-trained networks trained for different tasks such as BERT[4], or QuesNet [25]. These approaches directly use the response data of users to estimate the student performance.

Collaborative filtering aims to model users and items to predict potential user-item responses based on user-item interaction data [18]. Using the modeled user and item vectors, one can recommend items to a user that have high predicted labels [17]. Where matrix factorization is widely used due to the simple implementation, neural network models are also suggested to capture more complex features in user-item interactions [7]. The authors of [11] suggested a collaborative filtering based approach to predict the probability of a student answering to a question correctly.

Some methods are based on domain expert knowledge such as Knowledge Graphs, tagging of contents, or expert designed rule based models [5]. Martin, et al.[12] proposed a method to use the Bayesian network that reflects rules designed by domain experts. Item Response Theory(IRT) can be applied by tagging items with their difficulty, or knowledge requirements [10], [20].

2.2 Pairwise Comparison based Models

Supervised learning (regression and classification) is the process of predicting labels of instances using the features of instances. The features of instances can be structured (nominal, ordinal), or unstructured(image, text, sound). Some models also utilize features that are not from the instance themselves by *pre-training* methods. Pre-training is to train a model on an unsupervised auxiliary task and use the trained model to perform the supervised main task [6].

However, there are also models that predict the labels using pairwise comparisons of instances, without using the features from the labels. An instance of a pairwise comparison based assessment method is Comparative Judgement (CJ). The concept was first introduced by Thurstone [22] in the context of Psychological assessment. CJ takes the order comparison data (high or low) of instance pairs to fit a 1-dimensional ordered label of instances. This method is especially effective in domains where there is no standardized assessment method, such as essay marking, image quality assessment [24], [15]. For instance, the authors of [15] performed a major experiment asking professional markers to give comparisons, instead of direct markings. Performing Adaptive Comparative Judgement shows better reliability,

Figure 1: The training step

Figure 2: The inference step

and speed than traditional marking in particular areas such as essay marking [16], and mathematics problem solving [9]. Comparative judgement techniques are also applied in areas such as Psychology, Education [19], [9], [14]. The authors of [23] designed a neural network from pairwise comparison data to solve a regression problem, where the features and labels are uncoupled. They make pairwise comparisons of 1-dimensional values to predict the label. We generalize this idea to build models that use multi-dimensional features of pairwise comparisons to predict the label.

3. PROPOSED METHODS

We propose a method to predict the label value of a user. It reflects the responses of the user to items, using pairwise comparisons of responses with other reference users. Possible examples of the labels are preferences on items, expected response values, performance levels on a task, or knowledge levels. The main idea is to model the relative relation of user pairs by the features of pairwise comparisons, as in Figure 1. The arrows between users describe pairwise comparison results, and two users with no arrow in between are incomparable users. For inference, the comparisons of a target user to multiple reference users is used to predict the label of the target user, as in Figure 2.

3.1 Data Description

We use the *EdNet KT1* open dataset [2], which has 95M rows, with columns *userId*, *questionId*, *correctness*, *timestamp*. We do not use any other data source for label data for the experiments to be reproducible from open data. Therefore, note that the following steps to construct labels are not an essential part of the proposed method. If labels of users are available in another experiment setting, then those labels can be used without this additional process. The labels from *EdNet KT1* for this experiment are constructed from the response data by the following procedure:

We sort the items by their total count in the response dataset in decreasing order. Then, we take the first 50 items. Filter the raw data by users who responded to all 50 items, and compute the correctness rate of 50 items and use it as the

label. Filter the raw data by users who responded to all 50 items, and filter out the responses on the chosen 50 items for the experiment.

3.2 Proposed Methods

Before we introduce the details of the proposed models, we describe an example case of the models to illustrate the underlying idea. Consider a case where we have user-item interaction data with columns *userId*, *itemId*, *correctness* as in the *EdNet KT1* data case. Fix two users u_1, u_2 and let TT, TF, FT , and FF be the number of items that both u_1, u_2 responded correctly, only u_1 responded correctly, only u_2 responded correctly, both u_1, u_2 responded incorrectly respectively. If $TT = 90, TF = 10, FT = 110, FF = 40$, then u_1 correctly responded to 90% of the items that u_2 correctly responded, where u_2 correctly responded to 45% of the items that u_1 correctly responded. This relation shows an aspect that the knowledge of u_1 includes the knowledge of u_2 more than the other way round. Then, let y_1, y_2 be some label that reflects the educational performances of users u_1, u_2 . Then, we can consider a model that takes TT, TF, FT, FF and y_2 as features to predict the label y_1 . This model is an example of the first proposed model that we introduce later in this section. The second model that we propose is based on comparisons with multiple users. The main idea is to predict a label from multiple comparisons with other reference users. Now we describe the details of the pre-processing procedure for the proposed models in the general setting.

Consider the general case where we have response data with columns: *user_id*, *item_id*, *response*, where the possible responses of users to items are $1, \dots, r$. We show sample tables for each step of the whole process starting from Table 1.

user_id	item_id	response
1	19	1
1	23	r
2	77	2

Table 1: Raw data example

Fix N items to use as the labels, and filter out responses which have *item_id* in those N items. Group by *user_id* and make r arrays l_1, \dots, l_r where each l_i is the array of *item_ids* that is responded as i . Then, append the label columns y_1, \dots, y_N to this table.

user_id	l_1	...	y_1	...	y_N
1	[19,35,63]	...	0.84	...	0.72
2	[4,19,88]	...	0.30	...	0.54
3	[9, 17]	...	0.76	...	0.66

Table 2: User Table Example

This table has columns *user_id*, $l_1, \dots, l_r, y_1, \dots, y_N$. Now, we fix *reference users*, which is a subset of the users in the User Table. Then, filter the User Table by the users in the *reference users*.

Join the User Table with the Filtered User Table by the *user_id* column of each table to obtain the table with columns *user_id_1*, *user_id_2*, and

$$l_{1,1}, \dots, l_{r,1}, l_{1,2}, \dots, l_{r,2}, y_{1,1}, \dots, y_{N,1}, y_{1,2}, \dots, y_{N,2}.$$

user_id	l_1	...	y_1	...	y_N
1	[19,35,63]	...	0.84	...	0.72
16	[2,64,85]	...	0.89	...	0.78
22	[100,101]	...	0.24	...	0.42

Table 3: Filtered User Table Example

Then, for all $1 \leq i, j \leq r$, append the lengths of the intersections of the array pairs $l_{i,1}, l_{j,2}$ as $x_{i,j}$. Drop the columns *user_id_1*, *user_id_2*, and $l_{1,1}, \dots, l_{r,1}, l_{1,2}, \dots, l_{r,2}$, which finally leaves only the following columns:

$$x_{1,1}, \dots, x_{r,r}, y_{1,1}, \dots, y_{N,1}, y_{1,2}, \dots, y_{N,2}.$$

$x_{1,1}$	$x_{1,2}$...	$x_{r,r}$...	$y_{1,1}$...	$y_{N,2}$
25	42	...	34	...	4	...	12
6	22	...	72	...	10	...	28
15	34	...	2	...	1	...	40

Table 4: Pair Table Example

We call this table with $r^2 + 2N$ columns the Pair Table, and we use this table for model training, where the feature columns are $x_{1,1}, \dots, x_{r,r}, y_{1,1}, \dots, y_{N,1}$, and the label columns are $y_{1,2}, \dots, y_{N,2}$.

Now we introduce the proposed models: PC_1 , and PC_M . The first model PC_1 is a model that predicts the label of a user by comparison with a single other user. The model uses $x_{i,j}$ and $y_{k,1}$ for features, where $i, j = 1, \dots, r$, and $k = 1, \dots, N$. The N -dimensional labels are $y_{k,2}$ for $k = 1, \dots, N$. When $r = 2$, we call $TT = l_{1,1}, TF = l_{1,2}, FT = l_{2,1}, FF = l_{2,2}$. Note that each row of the input data is a comparison with one other user.

The second model PC_M uses pairwise comparisons $l_{i,j,k}$ for M multiple users $k = 1, \dots, M$ as features. The labels are the columns y_1, \dots, y_N of a fixed user. In this model, each row of the input data is the collection of comparisons with multiple users. Then, the loss function is computed by the L1 norm of the N dimensional prediction error. We used a simple fully connected network structure:

- FC($N + r^2$, 64), ReLU
- FC(64, 32), ReLU
- FC(32, N)

3.3 Inference using the proposed model

To predict the labels of a new user u with responses l_1, l_2, \dots, l_r , we compute the join of this row with the User Table to make the Pair Table of u , by following the steps in the previous subsection. The created Pair Table is the table of pairwise comparisons of user u , with the other users in the User Table. Feeding the processed features to the proposed models PC_1, PC_M give the predictions of the labels.

3.4 Neural Network baseline models

Our baseline model is a simple neural network model based on *Fully connected feed-forward network*. The network parameters are set to match the network we proposed above

in 3.2. The hyperparameters, which include the model dimension and depth, have been fit to yield the best results. The Neural Network baseline model takes all user responses as input. We name this model *NaiveFC*. In *EdNet KT1* dataset, there are 3 possible labels for each question. 1 for correct response, 2 for incorrect response and 0 if there is no response. Each value is embedded into a latent space, and the embedded values are added as an input to the model. We find the best performance when the latent space dimension is 128.

3.5 Matrix Factorization and Random Forests as Baseline

We also train a Matrix Factorization (MF) model using Alternating Least Squares [21]. In the proposed models, we split users into train/validation, or train/validation/test. However, matrix factorization models cannot be trained to optimize the results on the validation set, since the user-item embedding of only the validation set will be trained. This leaves the data on train users to be ignored. Therefore, we train the MF model on *train + validation* users and evaluate on *validation* users. This method of data feeding gives higher accuracy since the validation data is included in the train data. Therefore, Matrix Factorization is not a proper baseline for direct comparison because of train-test data cheating. Still, the results are listed as a comparison of the proposed models. We also train a Random Forest Regression model, with maximum depth 30 and the number of trees 300. Likewise, any other regression model can be used after the pre-processing steps.

4. EXPERIMENTS AND RESULTS

From the *EdNet KT1* dataset, we filter the responses from the users who have solved all the 50 most-responded items. The filtered data consists of 9,539,455 responses from 3692 users. To evaluate the data efficiency of our model, we compare the performance of our model while varying the minimum number of responses of each user in the data. The minimum number is varied by 50, 100, and 200, which is the number of responses after excluding the responses for the 50 items. For each setting, the total dataset is filtered by the users who responded more than the minimum number. Then, the users are split into *train* and *test* users by 9:1.

In the PC_M case, we construct three cases for the size of reference users, which are 8/9, 1/9, and 1/90 randomly sampled users from the *train* users in the filtered dataset. These numbers correspond to 80%, 10%, and 1% of the total users. The PC_M models are named by the portion of response users, and the minimum number of responses excluding the label items. For instance, PC_M50 80% corresponds to the case where the users are filtered by those who answered more than 50 questions excluding the label items, and 80% of the total users are randomly assigned as reference users.

We compare the results with the baseline models *NaiveFC*, Random Forest, and a constant value model. Both *NaiveFC* and Random Forest models take the vector with each element representing the response value of non-label items as input. There are 10782 columns that are used as features, since there are 10832 items in total. The constant value model predicts everything as the average of the labels of the

training dataset. The models are trained to predict the label column, which is the correctness rate for 50 label items.

All proposed models based on pairwise comparisons show better performance compared to the baseline models *NaiveFC*, Random Forest, and Matrix Factorization. From the experiments on PC_M , we show that the reduction of 98.75% reference users, also resulting in 98.75% reduction of the feature columns in a different sense, shows similar levels of performance. The 1% reference user case, where there are only 32 reference users, surpasses the performance level of the baseline models, and also shows similar level of performance with more reference users.

The first Matrix Factorization model is trained by the test data included in training, and evaluated by test data. The second model is trained by test data, and evaluated by the same test data. When predicting all the values as the average label values of the training dataset, the MAE for test dataset is 0.1498.

Model	MAE _{train}	MAE _{test}
PC_1100	0.0956	0.0974
PC_1200	0.0955	0.0974
PC_M50 80%	0.0956	0.0973
PC_M50 10%	0.0956	0.0969
PC_M200 10%	0.0956	0.0974
PC_M50 1%	0.0958	0.0966
PC_M200 1%	0.0954	0.0968
NaiveFC	0.1560	0.1648
Random Forest	0.0379	0.1011
MF(Test in Train)	0.3391	0.2437
MF(Trained by Test)	0.1872	0.1872
Average	0.1519	0.1498

Table 5: EdNet Results

5. CONCLUSION AND FUTURE WORK

We have presented two assessment models PC_1 and PC_M based on pairwise comparisons. Experiments show that the proposed models give good results in the *EdNet KT1* case. The features TT, TF, FT, FF capture the relative ordering of the educational performance, as described in the beginning of Section 3.2.

Our method can be applied in any domain where multi-dimensional features capture a uniform ordering of labels, as in the education assessment case. To apply the methods to other problems, one can simply exploit the pre-processing method described in the paper for different labels. The experiments of this paper use labels constructed from the response data, but note that this process is made before applying the proposed models. By using external labels, one can skip the label constructing process and simply feed the pairwise comparison features to the proposed models.

Also, this paper only presents the performance of our models using user response data of *EdNet KT1* as features. We presented a baseline of our approach. Further experiments can be made on other open data such as *ASSISTment*. In our expectation, by leveraging richer data into the features, such as time spent for solving a problem and user behaviors

during solving problems, the accuracy of the models would be improved. Also, adjoining pairwise comparison features to existing real-world models can be a way to reduce the inference cost, as well as label data gathering cost. We leave this as our future work.

ABSTRACT

We propose edit distance trail as a representation for analyzing the behavior of students solving Parsons puzzles. The edit distance of a student's solution from the correct solution of a Parsons puzzle gives the degree of correctness of the student's solution. Edit distance trail of a student's solution is the chronological sequence of edit distances of the student's solution from correct solution after each puzzle-solving action. We used edit distance trail representation to analyze the puzzle-solving behavior of students who used a Parsons puzzle tutor on `while` loops. In order to find patterns in student solutions, we applied k-means clustering with elbow method. We found that the centroid curves of the clusters of complete solutions differed by slope, corresponding to the degree of optimality of student solutions. Students found the final few steps of the solution to be more challenging. Centroid curves of clusters of incomplete solutions separated informed attempts from uninformed attempts and identified when students hit a dead-end. We discuss the advantages and drawbacks of our representation as compared to aggregate graphs used in literature and how edit distance trails can provide insight not afforded by descriptive statistics.

Keywords

Edit-Distance, K-means clustering, Patterns in puzzle solutions

1. INTRODUCTION

In a Parsons puzzle [4], the student is given a program with its lines scrambled and asked to reassemble the lines in their correct order. The student is also asked to delete one or more distracters – lines of code that do not belong in the program. These puzzles are rapidly gaining popularity in introductory programming courses. Students preferred solving Parsons puzzles to answering multiple choice questions or writing code in electronic books [3]. Educators like Parsons puzzles because solving puzzles takes significantly less time than debugging code or writing equivalent code, but in one study, it resulted in the same learning performance and retention [2]. Scores on the puzzles were found to correlate with scores on code-writing exercises in another study [8]. Software to administer Parsons puzzles have been developed for programming languages such as Turbo Pascal [4], Python

(e.g., [7,10]) and C++/Java/C# [1].

The sequence of actions taken by students to solve Parsons puzzles can potentially yield insight into their puzzle-solving strategies, just as similar analysis has been proposed for code-writing tasks (e.g., [5]). If patterns can be found in how students go about solving the puzzles, the patterns may in turn be used to predict the likelihood that a student can successfully solve a puzzle, and to provide customized feedback that helps a struggling student get back on track to correctly solve a puzzle. In other words, analyzing how students solve these puzzles could be beneficial to educators, students and researchers.

Whereas the solution to a Parsons puzzle is a state, the sequence of actions taken to solve a puzzle is a path. To date, to the best of our knowledge, only one study has been carried out to analyze the path taken by students to solve Parsons puzzles [6]. In the study, researchers built a visualization of the solution paths used by students and found wide variance among student solutions. They built aggregate graphs of all the solution paths for each puzzle. In the graphs, nodes were puzzle states, the size of each node being proportional to the number of students who had visited that state. The nodes were color-coded based on correctness. Similarly, edges represented state transitions in student solutions, with the width of each edge proportional to the number of student solutions that included the transition. The researchers found sub-optimal puzzle-solving behaviors such as backtracking and circular looping that could be targeted with customized feedback.

This analysis based on puzzle-states can yield puzzle-specific patterns, such as the statement(s) in a puzzle that students have the most trouble assembling. But, since a puzzle with n statements can have $n!$ states, the aggregate graph of the puzzle can be sparse, making it harder to find patterns in student solutions. For the same reason, this approach does not scale well to larger puzzles, i.e., puzzles with more lines of code.

2. EDIT DISTANCE TRAILS

As an alternative to aggregate graphs, we propose to use **edit distance trail**. An edit distance trail is the sequence of edit distances of student's solution from correct solution, one edit distance per action taken by the student to solve the puzzle. In other words, it is a record of edit distances of the student's partial solution from the correct solution from start to finish. In order to find patterns in student solutions of a puzzle, we propose to use **k-means clustering** of edit distance trails with elbow method for determining the value of k .

The operations allowed in a Parsons puzzle are 1) insertion of a statement into the solution 2) deletion of a statement from the solution and 3) reordering of a statement within the solution. The edit distance of a student's solution from the correct solution is

Salil Maharjan and Amruth Kumar "Using Edit Distance Trails to Analyze Path Solutions of Parsons Puzzles" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 638 - 642

the number of these actions necessary to reach the correct solution from the student solution.

In order to calculate edit distances, we modified Levenshtein's algorithm [11]. Levenshtein's algorithm calculates edit distance based on three operations: insertion, deletion and substitution. Since substitution is not an operation permitted in Parsons puzzles, but reordering is, we modified the algorithm to eliminate substitution and incorporate reordering operation.

Edit distance trail of a student on a puzzle is the chronological list of edit distances of the student's partial solution from the correct solution after each action taken by the student to solve the puzzle.

- The starting edit distance of an empty student solution from the correct solution is equal to the number of lines in the puzzle. So, every edit distance trail starts with a value equal to the number of lines in the puzzle.
- When the student's solution is complete and correct, its edit distance from the correct solution is 0. So, every edit distance trail of a completed solution ends with 0.
- The length of the trail is one more than the number of actions taken by the student to solve the puzzle, the extra element corresponding to the start edit distance before the student has taken the first action to solve the puzzle.
- Since our modified Levenshtein's algorithm to compute edit distance treats insertion, deletion and reordering as single-cost operations, each insertion and deletion action increases or decreases the edit distance by exactly 1. A reordering action may change the edit distance by 0 if reordering is incorrect, or 1 if correct.
- If the student inserts a distracter into the solution, edit distance increases by 1.

Unlike the combinatorially explosive number of states in aggregate graphs [6], the length of edit distance trail is linear in the number of actions taken by the student to solve the puzzle. The result of this smaller state space is greater overlap among student solutions, making patterns in student solutions easier to find. Since edit distances abstract away puzzle-specific details such as program states and individual lines in a puzzle, edit distance trails are also amenable to comparison across puzzles.

3. A STUDY OF EDIT DISTANCE TRAILS

We used edit distance trails to analyze the data generated by a suite of tutors on Parsons puzzles called epplets (epplets.org) [1]. The tutors are adaptive and use pretest-practice-post-test protocol – every student solved all the pretest puzzles, but the tutors adaptively selected practice and post-test puzzles based on the learning needs of the student. Students used a drag-and-drop interface to solve puzzles.

For this study, we analyzed the data collected by an epplet on `while` loops. In the epplet, during pretest, students solved Parsons puzzles on the following concepts:

1. A puzzle containing a single `while` loop. The problem (id 2005) on which the puzzle was based was: "A program that reads numbers till the same number appears back to back. It prints the first number to appear twice back to back (e.g., 4 appears back to back in 3,7,5,7,4,4,5 and is printed)."
2. A puzzle containing nested `while` loops, the inside `while` loop's condition dependent on the execution of the outside

`while` loop. The problem (id 2105) on which the puzzle was based was: "A program that repeatedly reads a positive number, reads additional numbers till its multiple is found, and prints the number and its multiple. It repeats this until 0 or negative value is entered for the number. For example, while reading the sequence 3,2,4,6,2,5,4,0 it prints 3,6 and 2,4."

The tutor was used by introductory programming students as after-class assignments. For this study, we used the data collected by the tutor over eight semesters: Spring 2016 – Fall 2019. We included data from only the students who gave permission for their data to be used for research purposes. Students used the tutor in four different languages: C, C++, Java and C#. We combined the data from all four languages in our analysis. Students could use the tutor as often as they wished. When a student used the tutor multiple times, data from all the sessions was included in the study. In all, 1068 students used the tutor during those eight semesters.

Epplets log the sequence of puzzle-solving actions taken by each student. We processed these logs to reconstruct the partial solution after each action and compute the edit distance of the partial solution from the correct solution using modified Levenshtein's algorithm. After computing the edit distance trail corresponding to each sequence of puzzle-solving actions, we used k-means clustering to find patterns in the edit distance trails of the two puzzles (ids 2005 and 2105) separately. Within each puzzle, we analyzed edit distance trails of complete and incomplete solutions separately. The number of edit distance trails available for each puzzle and the optimal number of clusters found for each puzzle for complete and incomplete solutions are listed in Table 1.

Table 1. Number of Edit Distance Trails Available and Optimal Number of Clusters Found for each Puzzle

Puzzle No. (Id)	Complete Solutions		Incomplete Solutions	
	Trails	Clusters	Trails	Clusters
1 (2005)	532	3	239	4
2 (2105)	180	3	153	4

3.1 Puzzle 2005

The clusters found for complete solutions of puzzle 2005 are shown in Figure 1, along with their centroids, which are themselves trails. Table 2 lists the three clusters, number of solutions in each cluster, and the minimum, maximum and mean number of actions taken in those clusters to solve the puzzle.

The puzzle contained 13 lines of code and 2 distracter lines. So, all the centroid curves in Figure 1 start at 13. Data points in the figure at 14 or 15 correspond to the start of trails in which students inserted one or both distracters into the solution before inserting any lines of code that actually belonged in the solution. In the figure, each data point is part of one or more trails – when a data point is shared among trails of different clusters, the colors of the different clusters have blended.

Since a puzzle with n lines can be optimally solved with n actions, cluster 1 (leftmost centroid curve in Figure 1) with a mean of 17.20 actions included all the optimal solutions. The centroid curves of the other two clusters have shallower slopes, corresponding to the use of more actions than necessary to solve the puzzles.

Figure 1. Clusters of Complete Solutions of Puzzle 2005.

Table 2. Complete Solution Clusters of Puzzle 2005 (13 lines):
Number of trails, minimum, maximum and mean actions taken to solve the puzzle

Cluster Number	N	Actions to Solve the Puzzle		
		Minimum	Maximum	Mean
1	383	16	28	17.20
2	112	20	40	27.25
3	24	31	73	40.12

The clusters found for incomplete solutions of the first puzzle are shown in Figure 2. Table 3 lists the number of incomplete solutions in each of the four clusters, the minimum, maximum and mean number of actions taken in the solutions of the clusters and the mean of the final edit distance of all the solutions in the cluster. The final edit distance shows how many more actions were necessary to complete the solution.

Cluster 2 corresponds to student who bailed out after a maximum of 3 actions. It is likely that these students were familiarizing themselves with the user interface of the puzzle and planned to return to use it in seriousness later. Cluster 3 (leftmost centroid curve) comprised of students who made quick progress (mean of 9.90 actions), but reached a plateau at the end before bailing out. They had an average of 9.58 steps left to complete the puzzle. Cluster 1 (second centroid curve from the left) comprised of students who made gradual progress towards the solution (mean of 21.05 actions) before bailing out. The students in this cluster took more actions to solve the puzzle than students in cluster 3, but got closer to the complete solution. Cluster 4 (rightmost centroid curve) was comprised of students who were lost from the beginning. Note that the *slopes of the centroid curves of incomplete solution clusters provide qualitative information about incomplete solution attempts in the cluster*: attempts that were informed (steep slope) versus those that were uninformed and included a lot of redundant actions (shallow slope), and the point at which attempts in a cluster hit a dead-end (plateau).

Figure 2. Clusters of Incomplete Solutions of Puzzle 2005.

Table 3. Incomplete Solution Clusters of Puzzle 2005 (13 lines): Number of trails, minimum, maximum and mean actions taken to solve the puzzle

Cluster Number	N	Actions to Solve the Puzzle			Mean final distance
		Min	Max	Mean	
1	78	12	43	21.05	7.05
2	65	1	3	1.50	12.95
3	53	4	27	9.90	9.58
4	38	23	75	32.18	8.63

3.2 Puzzle 2105

Figure 3 and Table 4 show the clusters found among complete solutions of Puzzle 2105, which contained 16 lines of code and 2 lines of distracters. So, complete solution edit distance trails started with a value in the range 16-18 and ended with 0.

The leftmost centroid curve corresponds to cluster 1, which contains all the optimal solutions, and yet, has an average of 22.2 actions. The rightmost centroid curve corresponds to cluster 2, wherein, students were able to solve the puzzle but took almost twice as many actions as cluster 1. The middle centroid curve corresponds to cluster 3, which included students between the other two clusters in terms of the mean number of actions taken. *Clustering of complete solutions resulted in centroid curves with varying slopes, corresponding to solutions at different levels of optimality.*

Table 4. Complete Solution Clusters of Puzzle 2105 (16 lines):
Number of trails, minimum, maximum and mean actions taken to solve the puzzle

Cluster Number	N	Actions to Solve the Puzzle		
		Minimum	Maximum	Mean
1	112	20	33	22.22
2	36	33	66	44.58
3	42	26	42	33.71

Figure 3. Clusters of Complete Solutions of Puzzle 2105.

Figure 4 and Table 5 show the clusters found among incomplete solutions of puzzle 2105. Cluster 1 represents students who bailed out early, with a maximum of 4 actions. Students in cluster 4 (middle centroid curve) got closest to the correct solution while taking more than twice the number of actions needed to optimally solve the puzzle. Students in cluster 2 (rightmost centroid curve) were less-prepared than those in cluster 4: they took nearly 50% more actions, but were still not as close to the final solution when they bailed out.

Table 5. Incomplete Solution Clusters of Puzzle 2105 (16 lines): Number of trails, minimum, maximum and mean actions taken to solve the puzzle

Cluster Number	N	Actions to Solve the Puzzle			Mean final distance
		Min	Max	Mean	
1	54	1	4	1.24	17.05
2	18	34	84	48.50	10.11
3	26	5	27	10.30	13.34
4	53	18	51	33.88	7.07

Figure 4. Clusters of Incomplete Solutions of Puzzle 2105.

4. DISCUSSION

Analysis of complete solutions of both the puzzles yielded three clusters corresponding to different levels of optimality of the

solution: one cluster corresponding to optimal solutions, and the other two differing in the number of unnecessary actions taken by students to solve the puzzle. Analysis of incomplete solutions yielded four clusters, one of them corresponding to “lurkers” – students who just tried a few actions before bailing out. Lurkers are similar to “stoppers” identified in literature [9] – students who do not take any actions once they encounter a problem, although we believe lurkers were probably just testing the interface. “Movers” identified in literature [9] were all the students in complete solution clusters who were able to solve the puzzle by gradually taking steps towards the correct solution. “Tinkerers” [9] were students in incomplete solution clusters who tried to solve the problem by making small changes in the hopes of making it work.

Edit distance trails can be used to further analyze the behavior of movers and tinkerers. For instance, all the centroid curves in complete solution clusters show a tail at the end of a steep slope. This suggests that even movers who make steady progress solving a puzzle find the last few steps to be more challenging. One possible explanation is that at the end of solving a Parsons puzzle, the student is left with only one or two lines to insert, but the number of locations where they can be inserted are the most ever, making the final steps more challenging.

This illustrates an example of when edit distance trails are more informative than descriptive statistics such as the number of steps taken to solve a puzzle: even in a monotonically decreasing edit distance trail, a change in slope may hint at a moment of frustration (transition from slope to plateau) or insight (transition from plateau to slope). A non-monotonic trail with frequent up-and-down-swings may suggest the use of trial-and-error approach. Such differences may be found in the trails of two different students even when they may have taken the same number of steps to solve a puzzle.

Edit distance trail representation is at a more abstract level than aggregate graph representation reported in literature [6]: using edit distances eliminates puzzle-specific details such as the specific line of code acted upon at each instant by a student. So, aggregate graph representation is better at unearthing puzzle-specific patterns such as determining the specific lines of code that most students might have problems assembling correctly. Edit distance trail representation on the other hand makes it easier to identify patterns among solutions – optimal versus sub-optimal complete solutions, lurking behavior, etc. because of its smaller state space. In the future, with the accumulation of additional data, we hope to find more patterns among complete and incomplete solutions that will provide more qualitative information about the types of solutions.

ABSTRACT

In the context of online education, one important consideration is ensuring learning is equitable for a diverse range of students. In particular, understanding how factors such as gender and age can affect student behaviour is crucial for adapting courses to better suit the needs of these students. In this paper, using data from an online introductory programming course, we apply hierarchical clustering to identify changes in student behaviour as students approach dropping out from a course. By considering how these behavioural trends differ based on gender and school year level, we then discuss how this information can lead to insights to assist in improving equity and educational outcomes.

Keywords

gender equity, age equity, student dropout, student behaviour, computer programming education, behavioural trends, hierarchical clustering

1. INTRODUCTION

In an educational setting, ensuring that all students receive equitable learning opportunities is a challenge of great significance. This is particularly important in the context of online education, where teachers may be unable to personally monitor all students due to large cohort sizes, and where the increased accessibility of course materials can allow for very diverse ranges of students. It is also particularly important in areas where certain groups are under-represented, since inequitable education may discourage students from these groups from entering the field. Recent work on improving educational equity has often focused on improvements at an organisational level, such as through teacher training [11], frameworks for addressing equity challenges [7] or analyses of funding distributions [2].

A particularly promising avenue for improving educational equity is the analysis of student behaviour. In particular, educational data mining and analysis techniques can

be utilised to understand how students from different backgrounds respond differently to a course, thereby providing insight into how the course can be modified to improve learning outcomes and equity. Previous work employing such techniques has considered, for example, differences in behaviour at school and home [4], course enrolment and completion rates [10], social behaviour [3], online participation and activity [6, 9], debugging techniques used [8] and motivation for study [5] for different student groups.

In contrast to previous work, this paper uses a hierarchical clustering technique to analyse the evolution of behaviour of students who drop out of an introductory programming course. In particular, samples of student behaviour are taken at different stages during a course (e.g. when they first begin, at points midway through and just before they drop out). These samples are then clustered to detect changes over time and to compare students of different gender and grade groups.

2. DATA

Our data come from a beginner-level Python programming course run in 2018. The course was run online for school students primarily in Australia over a 5 week period, and consisted of weekly exercises interleaved with notes on different topics. In total, this amounted to 40 exercises. Of the 6516 students who attempted the first exercises of the course, 82% dropped out before completing the last exercise.

3. METHODOLOGY

To observe how student behaviour changed as students came closer to dropping out, we analysed the behaviour of all students who completed at least 10 exercises in the first four weeks of the course but still ended up dropping out. These students were selected because they were more likely to be seriously attempting the course (10 exercises constituted 25% of the course), so their dropout was particularly significant. In addition, there would have been more opportunities for interventions to assist these students, so insights from their behaviour could potentially have a larger impact on similar students in future. We considered the first four weeks of the course since all the exercises were comparable (i.e. structured similarly with a similar time limit to complete them). In total, 3677 students were selected.

For each of these students, we then selected a sample of evenly spaced out exercises from the set of exercises they completed during this time, which would represent their

Jessica McBroom, Irena Koprinska and Kalina Yacef "How Does Student Behaviour Change Approaching Dropout? A Study of Gender and School Year Differences" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 643 - 647

behaviour at different stages during their interaction with the course (e.g. when they first began, midway through or just before dropping out). Since all of the selected students had completed at least 10 exercises, we used a sample of 10 evenly spaced out exercises for each student, which was the maximum we could select without including missing data for some students. Since the first and last completed exercise are particularly important when analysing dropout, we wanted to include both of these for each student. As such, we selected exercises using the following process: for each student let $e_1, e_2 \dots e_n$ be the n exercises they completed ($n \geq 10$). Then, define $f(k) = \text{round}(1 + \frac{k(n-1)}{9})$ and select $e_{f(0)}, e_{f(1)}, \dots, e_{f(9)}$. For example, if a student completed 20 exercises, the selected exercises would be $e_1, e_3, e_5, e_7, e_9, e_{12}, e_{14}, e_{16}, e_{18}$ and e_{20} .

After selecting 10 representative exercises for each student, we then generated features to describe their behaviour during each of these exercises, as shown in Table 1. These features related to the number of times particular events occurred, such as viewing the exercise or failing it, and the timings of these events. Note that these features did not need to be independent due to the clustering technique used.

Table 1: Features used to perform the clustering

Feature	Description
num views	the number of times the student viewed the exercise page
num autosaves	the number of times the student's work was autosaved (this was triggered if they had unsaved work that was not modified for 10 seconds)
num failed	the number of times the student submitted their work for marking but did not pass all automated tests
earliest: view, autosave, failure and pass	the time of the first view, autosave, failure or pass respectively (in seconds, relative to the deadline)
average time between fails	if the student failed the exercise two or more times, the average time between these failures, in seconds
time from first failure to completion	if the student ever failed the exercise, the time in seconds from this point until these passed.

After preparing the features, we applied the temporal hierarchical clustering algorithm DETECT [1] to find clusters of student behaviour that changed over time. This algorithm produces hierarchical clusters defined by decision rules (e.g. a cluster could be all cases where the number of views was ≤ 3 and the number of fails was > 2). To do this, it performs a search over many different options for clustering the data, each time observing the resulting distribution of clusters over time. It then chooses the option that maximises an objective function based on this distribution. In this case, the objective was to find clusters that changed the most between the student's first two sample exercises and their last two. Since the algorithm selects only the best features in the final clustering, the method is robust to dependencies between features. The resulting clusters are shown in Figure 1 and discussed in more detail in the next section.

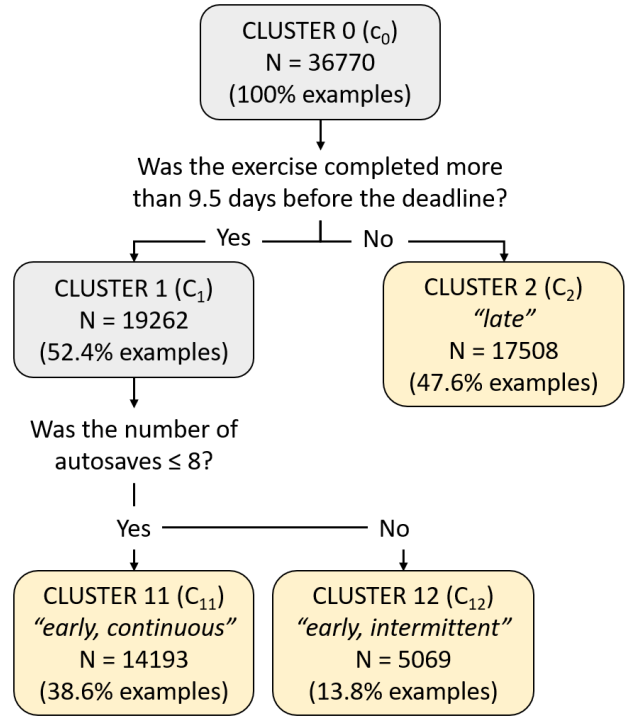

Figure 1: Hierarchical clusters of student behaviour. The cluster names show the hierarchical nature of the clusters. Cluster 2 represents cases where students completed the exercise late. In contrast, Clusters 11 and 12 represent cases where students completed the exercise early and worked continuously and intermittently respectively. This is discussed in further detail in the text.

After producing the clusters, we then analysed the differences in cluster distributions for students from different backgrounds. In particular, we considered the relationship between student gender and school year level on the cluster distributions over time in order to gain insight into equity issues. The results are discussed in the next section.

4. RESULTS AND DISCUSSION

4.1 Behavioural Clusters

The behavioural clusters produced by DETECT are shown in Figure 1. The cluster names indicate the hierarchical nature of the clusters: c_0 at the root contains all examples, c_1/c_2 are mutually exclusive subsets of c_0 and c_{11}/c_{12} are mutually exclusive subsets of c_1 . Since there were 3677 students in total and 10 representative examples for each student, this made $N = 3677 \times 10 = 36770$ clustered examples of behaviour in total, with 38.6%, 13.8% and 47.6% in c_{11} , c_{12} and c_2 respectively.

In this work, we focus on the three final clusters, c_{11} , c_{12} and c_2 , which we label for convenience as “early, continuous”, “early, intermittent” and “late” respectively. We label c_2 as “late” since it represents cases where students completed the exercise close to the deadline (i.e. within 9.5 days of it). In contrast, c_{11} and c_{12} are labelled as “early” since here students completed the exercise more than 9.5 days before

the deadline. In addition, c_{11} is labelled as “continuous” because there were ≤ 8 autosaves, and these were triggered when a student with unsaved work paused for more than 10 seconds. As such, a student with a small number of autosaves did not pause very often and worked continuously. In contrast, we label C_{12} as “intermittent” since there were a large number of pauses.

Since we used a sample of 10 exercises for each student, this meant that students could move from cluster to cluster over time. As such, in order to understand how the cluster distributions changed over time, we plotted the number of students in each cluster for each exercise, as shown in Figure 2. Note that the total number of students in the graph is constant over time (3677 students). Note also that the exercises are relative to the students, not the course. For example, Exercise 1 and Exercise 10 represent the first and last exercise that each student completed before dropping out, not the first and tenth exercise in the course.

Figure 2: Cluster distributions over time

When submitting their first exercise, most students were in c_{11} (early, continuous), where they completed the exercise more than 9.5 days before the deadline and had ≤ 8 autosaves, indicating that the students worked continuously on the exercise. As such, dropping out students tended to complete the exercises early and continuously when they first began the course. Over time, however, the number of students in the other clusters increased. In particular, by the time they were close to dropping out, most students were in c_2 (late), where they were no longer completing the exercises early. In addition, the increase in c_{12} (early, intermittent) indicates that the students who did complete the exercise early paused more, possibly due to difficulty or distraction.

In summary, by clustering evenly spaced-out samples of student work over time, it is possible to observe how student behaviour develops as students approach dropping out. In the next sections, we will filter these students based on grade level and gender to observe differences in these trends for different student groups.

4.2 School Year Level Differences

In order to analyse the differences between students of different school year levels, we divided students into four groups based on school year, as shown in Table 2. Using the same clusters as before, we then observed the differences in cluster distributions with respect to these groups. The results are shown in Figure 3.

Table 2: Grade groups used in the analysis. N is the number of students in each group who dropped out but completed at least 10 exercises in the first four weeks of the course.

Group	N	Description
Year 11+	263	Senior students in Year 11 or above
Years 9-10	2090	Intermediate students in Year 9 or 10
Years 7-8	1081	Junior students in Year 7 or 8
Primary	238	Primary students in Year 6 or under

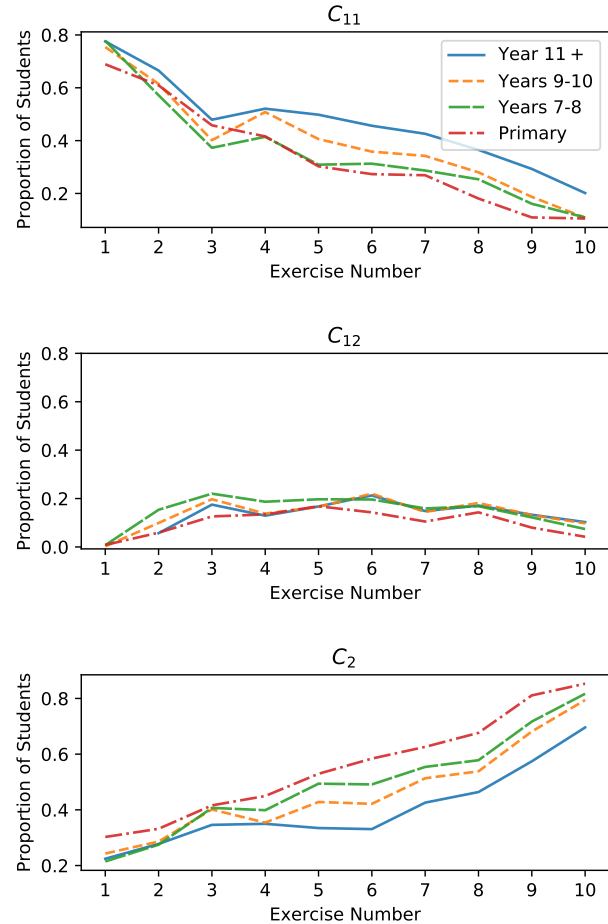

Figure 3: Differences in cluster distributions across school grade groups

From the graphs in Figure 3, one important observation is that increasing age is correlated with a decrease in the proportion of students in c_2 (late), and this difference increases over time. This suggests that younger students tend to complete exercises later than older students as they approach dropping out. This could suggest that younger students are more likely to drop out because they are falling behind and possibly having difficulties with time management, whereas older students may be dropping out for other reasons, such as losing interest or the exercises being too easy.

Another interesting observation is that, while most students were similar at the beginning, older students were more

likely to be in c_{11} over time than younger students. Since c_{11} represents behaviour where students complete the exercise early and work continuously, this suggests that older students may have been more organised than younger students, or found the exercises easier immediately before dropping out. This supports the idea that older students may have been dropping out because the exercises were too easy, while younger students may have done so due to difficulty.

These observations are important for informing future course development, since they can provide insight into how courses can be made more equitable. For example, if younger students are more likely to drop out from a course because it is difficult and they are falling behind, then interventions could be developed to help support these students. For example, they could be given extra practice questions or time to complete the exercises. In contrast, if older students were dropping out because the exercises were too easy, then more advanced content or optional extension exercises could be added for these students. This could then help to make the course more equitable by addressing the needs of different student groups.

4.3 Gender Differences

In addition to analysing differences based on school grade, we also considered how student behaviour differed based on gender. In total, we analysed data from 2334 male students and 1124 female students who dropped out after completing at least 10 exercises from the first four weeks of the course. The differences in cluster distributions over time are shown in Figure 4.

Figure 4: Differences in cluster distributions across gender groups

Interestingly, there is very little difference in the cluster distributions for male and female students over time for this course. This suggests that male and female students behaved similarly with respect to these clusters as they approached dropping out - they started the exercises at similar times and worked roughly as continuously as each other. The dropout rates for male and female students were also similar. Such information is highly valuable for improving gender equity, since it highlights where to focus attention. In particular, instead of comparing the behaviour of male and female students who drop out in order to introduce different types of interventions, perhaps focusing on reducing dropout in general for both groups, or focusing on improving the balance in enrolment rates, could assist in improving gender equity for this course.

5. CONCLUSION

In this paper, we have discussed how the behaviour of students who drop out from a course can be analysed in order to improve equity. In particular, representative samples of work from dropout students can be clustered to identify changes over time. Differences and similarities in trends as students approach dropout can then be observed for different student groups (e.g. male and female students or students from different grade levels). This comparison can lead to insights into the potential reasons for why students dropout, helping to inform further course development to improve equity.

Measuring task difficulty for online learning environments where multiple attempts are allowed – the Elo rating algorithm approach

Maciej Pankiewicz
Warsaw University of Life Sciences
maciej_pankiewicz@sggw.pl

ABSTRACT

The aim of this research is to examine the accuracy of the estimations performed with the Elo rating system in an online learning environment where multiple attempts are allowed and feedback is provided after every submission. The acquired estimations are compared to the reference difficulty values calculated by the means of the IRT graded response model. The data originates from the RunCode online learning environment (<https://runcodeapp.com>) developed for the purpose of learning programming skills. The platform has been made available to 299 first semester computer science students with varying initial programming knowledge. There have been 50055 attempts on 76 tasks recorded. Multiple attempts on tasks were allowed, there was no penalty imposed for extra tries and feedback was provided after every submission. High correlation values – up to 0.927 – have been observed for the estimations performed by the Elo rating algorithm. We argue that the design of the Elo algorithm makes it a good choice as the on-the-fly task difficulty estimation method for online learning environments where multiple attempts are allowed and feedback is provided after submission.

Keywords

Task difficulty, Elo, rating algorithm, gamification.

1. INTRODUCTION

There are several methods developed for the purpose of estimating task difficulty that originate to a great extent from the area of item response theory. Some aspects make application of these methods in the context of online learning environments difficult, e.g. computational demands or difficult implementation. Therefore alternative methods of the difficulty estimation are analyzed [1], with the focus on lower computational demands and easier implementation. The Elo rating algorithm is an example of such alternative methods that satisfies these requirements, however, often with the cost of lower (reasonably) estimation accuracy. In online learning environments with formative assessment approach – contrary to knowledge assessment systems – lower accuracy of the estimations may be often accepted. Such learning environments may benefit from the implementation of faster

methods, even if the requirement of high estimation accuracy is not met. The Elo rating system has already found several implementations in the educational context [1, 2, 3, 4]. However, most of the up-to-date research focuses on its applications within knowledge testing environments (summative assessment) or online learning platforms (formative assessment) where one attempt is allowed and with examples of task types presenting low complexity, e.g. multi-choice, where it is easy to satisfy the requirement of automated evaluation. The programming assignment is an example of a task type with much higher complexity – it is highly improbable to “guess” the correct answer for such a task type. It is, however, a task type that also satisfies a requirement of an automated evaluation and there are multiple types of automated tests that may be executed on the programming code in order to verify its correctness [5]. It is intuitively expected that on average, the number of attempts needed to correctly solve a programming task is much higher than of e.g. multi-choice task type. But how does it impact the quality of task difficulty estimation? What is the impact of multiple attempts, especially if there is a significant number of tasks available in the system on which learners fail multiple times? Especially online learning environments may benefit from the answer to this question. Dynamically changing number of system users and (or) of collaboratively added tasks make the on-the-fly requirement of the task difficulty estimation hard to satisfy already for a small number of system users and tasks – if using the well-known difficulty estimation methods originating from the area of e.g. item response theory. On the other hand, usage of alternative methods for difficulty estimation may satisfy the on-the-fly requirement, but often with the cost of lower accuracy. This cost however may be often accepted and this research contributes to the question of the above-mentioned compromise between accuracy and on-the-fly calibration requirements in online learning environments.

2. ESTIMATING DIFFICULTY

Models created for the purpose of estimating task difficulty originate mainly from the area of Computerized Adaptive Testing (CAT) domain. These models are used in order to optimize the process of knowledge assessment by lowering the number of tasks and time needed to determine learner's current knowledge level. There are two estimations evaluated: of a task difficulty and of a learner ability. Foundations for the development in this area have been laid by G. Rasch that formulated the single parameter logistic model with difficulty parameter [6, 7, 8]. The model and its variations under the name of the Item Response Theory (IRT) have been since utilized not only in educational [9], but also medical [10] or marketing [11] applications. In the era of the internet education, methods for estimating task difficulty have

Maciej Pankiewicz "Measuring task difficulty for online learning environments where multiple attempts are allowed -- the Elo rating algorithm approach" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 648 - 652

been used not only for the purpose of the knowledge assessment [12], but are increasingly present in the field of Intelligent Tutoring Systems [13] where they are used for the purpose of matching item difficulty to learner ability in order to optimize the process of knowledge acquisition and achieve so called adaptivity. There are several examples of adaptive online learning systems e.g. for learning factual knowledge in the field of geography [1] or mathematics [2]. There are various methods other than item response theory models used for the purpose of task difficulty estimation that have been evaluated within educational research community e.g. Elo rating algorithm [1, 2, 12], proportion correct [12, 14], learner feedback [12, 15] or expert rating [12]. It has been found that the accuracy of these methods may achieve values described as “accurate-enough” for the purpose of online learning environments [1]. Although in terms of requirements for knowledge assessment systems such accuracy may not always be accepted, it may be a reasonable choice for usage within online learning environments. Above mentioned methods present several weaknesses in terms of their usage within online environments, e.g. require large calibration samples or high computational demands (IRT models), require large number of votes (learner feedback) or availability of experts (expert rating), in the context of their usage within online learning environments some of them may be more reasonable than other, depending on specific aspects of an individual system requirements. This article focuses on the usage of the Elo rating system as it is the algorithmic approach and therefore easier to automate than methods that require involvement of a human, e.g. expert rating or learner feedback. Additionally, it has already been validated as a suitable tool for online learning environments [1]. It has been implemented e.g. in the system with multi-choice questions where one attempt is allowed. This research extends the up-to-date research by presenting results of the analysis performed on the example of the online learning environment with the assignment of higher difficulty level (programming assignment), where multiple attempts are allowed, feedback is provided after every submission and no penalty is imposed for extra tries.

3. ELO RATING ALGORITHM

The Elo rating system [16] has been developed for the purpose of measuring strength of players in chess tournaments. The aim of the algorithm is to calculate players’ rating change after every game. That change depends on outcomes of tournament games. Every player is assigned a rating that is usually a number between 1000 and 3000 that is a subject to change after every game. New rating is calculated by a formula:

$$R_n = R + K(O - P)$$

Where: R_n is the new value of the rating, R – the actual rating, O – game outcome (1 – win, 0 – loss), P – probability of winning the game and constant K – the value for chess tournaments is often 32. The probability of winning P is given as:

$$P = \frac{1}{1 + 10^{\frac{R_o - R_p}{400}}}$$

Where R_p is the rating of a player and R_o is the rating of the opponent. In the context of an online learning environment, we consider a tournament game to be a single submission of a

solution, a player – a learner that submits the solution and opponent – a task.

There are three possible outcomes of the chess game (win, loose, draw), but in the context of learning environment we only consider two outcomes: learner wins if the submission receives the maximum score or learner loses if the submission does not receive maximum score.

4. METHODOLOGY

4.1 Programming course

The RunCode online learning environment is an online application that supports automated validation of the correctness of programming code available at <https://runcodeapp.com>. It provides access to various courses consisting of programming assignments that are grouped into modules for the purpose of clarity. There are several gamification enhancements introduced to the platform aimed at keeping the user engaged.

4.2 Programming assignment

Students learn to code using the RunCode online learning environment by solving programming assignments. Every assignment requires a student to create a code containing a function that will be executed by the test runner in order to check its correctness. Task description defines requirements that the function should meet. Students submit the code containing the function and immediately (after its execution by the test runner) receive score and feedback. Score is calculated as the percentage of the tests, that ended with success to the overall number of tests performed on the code and is presented as a value in the range [0%-100%]. The feedback information is based on the information returned by the test runner and contains errors and warnings (if any) returned by the compiler and results of tests executed by the test runner containing information about the correctness of the submitted code. Only submissions with no errors, no warnings and satisfying requirements of all tests defined by the lecturer receive the maximum score (100%). Multiple submissions are allowed and feedback is provided after every submission.

4.3 Data

The data originates from the gamified course available on the RunCode online learning environment: a platform developed for the purpose of learning programming skills. The RunCode system supports automated evaluation of the submitted programming code. The RunCode platform has been made available as an additional, optional tool during the first-semester *Introduction to programming* course at the Faculty of Applied Informatics and Mathematics, Warsaw University of Life Sciences. The course is mandatory for the students of computer science and is realized in a traditional way – with lectures and computer classes. The main online tool for managing the course resources is the university’s moodle website. Although the RunCode platform usage was not mandatory and results obtained were not included in the final grade, majority of the students decided to use the system on regular basis. The course containing 76 programming tasks has been made available on the RunCode application. The data has been collected during two winter semesters: 2017/2018 and 2018/2019. During this period, 299 students with varying initial programming knowledge used the system. There have been 50055 attempts recorded in total. Multiple attempts were allowed with no penalty imposed on extra tries and feedback was provided

immediately after every submission. Students self-elected the order of solving tasks.

5. RESULTS

The data has been collected during two academic years: 2017/2018 and 2018/2019 and contains system usage data that originate from the RunCode platform and results of the survey on the declared initial level of programming knowledge. Before the course started, students took a survey and answered the question about perceived programming skill level – self-evaluation of their knowledge of basic programming concepts. It has been a surprising observation, that about one third of students of the first semester at the Faculty of Informatics declared having completely no previous experience with programming languages and more than a half declared having no (skill level 1) or little (skill level 2) previous programming experience (Table 1).

Table 1. Results of the pre-course survey on programming skill level: 1 – no previous programming experience, 5 – very extensive programming experience.

	1	2	3	4	5
2017 (n=110)	32.7%	24.5%	15.5%	15.5%	11.8%
2018 (n=159)	32.7%	25.8%	22.0%	11.3%	8.2%

The overall engagement of the students, measured as the number of user submissions on the RunCode platform has been presented in Figure 1. The overall engagement of students is considerably high with the average of 178 submissions (attempts) performed by a user.

Figure 1. Histogram of the number of attempts performed by users of the RunCode platform.

The following detailed analysis of the submission data (Table 2) for the purpose of clarity has been limited to seven first attempts (ca. 75% of all samples). This limitation is reasonable, as the effects visible on the first seven attempts are in general also reflected in the remaining data (e.g. dropout) with the long tail of even more than 50 attempts on a task. Two important observations may be made basing on the overall view of the data presented in Table 2. Firstly, the number of successful attempts overall is low. On average, the first attempt is correct only in 39% of submissions. If the first attempt was not successful, the success

rate for the second submission is 30% and with following attempts, the success rate decreases.

Table 2. The number of correct and incorrect attempts on assignments. The Total column is the cumulative sum of attempts. The Dropout column is the percentage of students that resigned to take another attempt.

Attempts	Incorrect	Correct	Total	Dropout
1	8259	5269	13528	-
2	5623	2389	21540	0,030
3	4045	1244	26829	0,059
4	2950	842	30621	0,063
5	2259	493	33373	0,067
6	1766	342	35481	0,067
7	1396	237	37114	0,075

It denotes, that the average difficulty level of tasks available on the platform may be perceived as high. Secondly, despite the fact that users fail to upload successful solution on the first attempt, they feel motivated and do not give up. The dropout rate is very low. Only 3% of the system users give up if the first attempt was not successful. As the number of submission increases, the dropout rate increases but even at the 7th attempt is reasonably low (7%). In order to compare the difficulty estimations calculated by the Elo rating algorithm with the reference values the Pearson's correlation coefficient has been used. Reference values for the following analysis have been calculated by the means of the IRT graded response model [17]. The graded response model is suitable for modelling polytomous response data and has been already introduced e.g. for the purpose of knowledge assessment on open-ended tasks with multiple attempts allowed [18]. It has been found that the estimations of the IRT graded response model are accurate already for sample size of $n = 200$ [20]. The encoding procedure of polytomous data for the purpose of this analysis was following: the user-task matrix for the i -th attempt on task n by user m has been filled with value of i , if the first submission was successful. If the second attempt was successful, the value inserted was $i-1$. Every following attempt needed to achieve the maximum score lowered the inserted value by 1. In this scenario if a learner does not succeed in a maximum allowed number of attempts, the inserted value is 0. The procedure does not distinguish between not taking the task and exhausting all available attempts with no success. The study on the effects of missing data on the accuracy of estimations performed by the graded response model may be found e.g. in [19]. The reference (IRT) values for the following analysis have been calculated on the full data set. The optimal value of the Elo uncertainty parameter K has been evaluated experimentally, similarly to [12, 14]. The highest correlation with estimation values calculated with the graded response model has been achieved for the value of $K = 3$. The PlayerRatings R package [21] with default values of the initial rating and rating deviation has been used to perform Elo algorithm calculations and RapidMiner – for the ETL data processing [22]. The highest correlation value – 0.927 – has been observed for cumulative data from three attempts on tasks (Table 3). The correlation calculated only on the data from the first attempt achieves low correlation of the value 0.565.

Table 3. Correlation of the difficulty estimations calculated by Elo algorithm compared to the reference values.

Att.	1	2	3	4	5	6	7
Cor.	0,565	0,887	0,927	0,908	0,892	0,873	0,852

With increasing number of attempts, the correlation decreases – correlation value calculated for the cumulative data from 7 attempts is 0.852 (Figure 2).

Figure 2. Correlation of the difficulty estimations calculated by Elo algorithm with the reference values.

6. SUMMARY AND DISCUSSION

The aim of this research has been to evaluate the accuracy of the Elo rating algorithm in terms of the task difficulty estimation. The analysis has been performed in order to verify the appropriateness of the method for its usage within online learning environments where multiple attempts are allowed and feedback is provided after every attempt. The source of the data has been the programming course available at <https://runcodeapp.com> – an online application developed for the purpose of learning programming skills. The analysis has been performed on the sample of 50055 attempts on 76 tasks submitted by 299 learners – first semester students of computer science. The data has been gathered during two academic years: 2017/2018 and 2018/2019. Although usage of the platform was not mandatory, a high level of engagement has been observed – the dropout rate for consecutive attempts was in the range of 3-7%. Students presented varying levels of initial programming knowledge, with about one third declaring no previous experience with programming. The highest correlation of 0.927 has been calculated for data containing three attempts on task. With an increasing number of attempts, the correlation value has slowly decreased. The obtained correlation level may satisfy the requirements of the online learning environment and estimations may be perceived as sufficient. Similar values of correlation have been already obtained in previous research – does it mean that the Elo rating algorithm may be a reasonable choice for estimating difficulty within online learning environments? Under circumstances described in the following, it may be. Contrary to online assessment applications where large calibration samples are required, requirements of online learning environments in terms of the accuracy may not be that strict – although delivering lower accuracy, the Elo algorithm is quick and it is the main advantage. Novel aspects of this analysis concern following factors: 1) it is based on the data

originating from the real online learning environment created for the purpose of fostering basic programming skills; 2) allowance of the multiple (unlimited) attempts on task and feedback provided after every submission; 3) high level of the task difficulty observed as the large average number of attempts required to complete the task. There are several considerations that may limit the interpretability of the results and their generalization that may be divided into three elements referring to the RunCode platform, users and task characteristics. The RunCode online learning environment is a gamified internet application. The aim of the implemented gamification elements is to engage platform users and motivate them towards reaching the maximum score on every task. Overall engagement of system users may be described as very high and the gamification may be an important source of the large user contribution. The number of students that give up after an unsuccessful attempt is very low and varies between 3% and 7% for the first 7 attempts (Table 2). It should be a subject for further analysis, if the results may be repeated if the number of dropouts in the data increases. The platform has been made available to the first semester students of computer science enrolled in the *Introduction to programming* course. The variety of the skill level is broad in the analyzed group. Although the first impression may be that students enrolled in the computer science track already have experience with basics of programming, student responses in the survey completed at the beginning of the course do not confirm this suspicion. One-third of the students declares to have absolutely no previous experience with any programming language, but there are also several students that have already mastered the basic programming concepts before joining the course. It is to be analyzed, if the observations from this study are repeated if users present equal (e.g. very low) initial knowledge on the subject. It is also to be considered, that the motivation of the computer science student to succeed in the *Introduction to programming* course may be reasonably higher than of an average user that joins any programming course at any publicly available online learning platform. Although usage of the platform was not mandatory and results obtained were not impacting the final grade, students used the platform very extensively. Therefore, it is to be analyzed if the observations made within a group that focused on the success in the course apply in other contexts. The overall difficulty level of the programming assignment available on the RunCode platform may be described as high. The submission process is very complex in comparison to e.g. multi-choice questions. Even easiest tasks (as perceived by the lecturer) received on average a higher number of attempts than initially expected. It may result from the fact that unexperienced learners that joined the course struggled from the beginning with too many new concepts: not only related to the basic rules of code preparation, but also e.g. to the technical aspects of creating code with usage of the integrated development environment (IDE). There is an additional outcome of the large average number of submissions on a task. The difficulty level may be estimated with higher granularity, even if the number of system users is low. On the other hand, if these tasks were made available outside of the university's course, on an online platform to the public, a high average difficulty level would possibly lead to learners' frustration and it would be expected that the dropout rate will be much higher. Future work will be aimed at comparing other methods of difficulty estimation satisfying the requirements of the on-the-fly calibration.

Social Media Mining to Understand the Impact of Co-operative Education on Mental Health

Mohammad S. Parsa and Lukasz Golab
University of Waterloo
{mohammad.parsa,lgolab}@uwaterloo.ca

ABSTRACT

Co-operative education is a form of work-integrated learning that includes both classroom study terms and paid work experience. Research on co-operative education focuses on its benefits to students, employers, and academic institutions. In contrast, we study the impact of co-operative education on students' mental well-being. To do so, we mine social media content on the Reddit platform, which includes, among many other topics, discussion forums for major U.S. and Canadian colleges. Specifically, we perform topic modelling of discussions related to mental health and co-operative education. We find that students report feelings of self-doubt resulting from a competitive co-op job market, especially when placed in entry-level jobs that are not related to their academic programs, and anxiety due to job interviews, especially when they coincide with exams and other academic deadlines.

1. INTRODUCTION

Co-operative education (co-op) programs combine academic content with paid work experience. For example, students may alternate between classroom study terms and work-terms. Co-operative education programs, both at the undergraduate and graduate levels, have become popular as they offer practical work experience for students and a talent pipeline for employers [3, 26].

Prior work has examined the effect of co-operative education on students and employers. From a student point of view, studies have illustrated the impact of co-op on skill and career growth (see, e.g., [22, 13]). From an employer point of view, there has been work on understanding employers' expectations (see, e.g., [4, 16, 19]). On the other hand, there is less work on the effect of co-op on students' mental well-being, aside from small-scale studies of specific issues such as failing to obtain co-op employment (details in Section 2). This is, however, a pressing issue as recent work reports a rise in mental health problems among college students [1].

To fill this gap, we analyze social media to discover what students say about the impact of co-operative education on their well-being. Specifically, we perform topic modelling of U.S. and Canadian university discussion forums on the Reddit social media platform (reddit.com), followed by a detailed inspection of topics related to co-op.

In contrast to prior work based on surveys of small groups of students from a single institution, our study is based on a large dataset containing student-generated social media content from over 50 institutions, and is not limited to specific issues or students in specific circumstances. Furthermore, it has been recognized that the anonymity of social media makes it suitable for discussing sensitive issues. However, while there has been prior work on using social media such as Reddit and Twitter to understand mental health issues [7, 5, 18, 15, 14, 21, 8], including issues experienced specifically by students [1], these studies have not reported any issues related to co-operative education.

Our main findings are as follows. First, we find indications of self-doubt resulting from competition, specifically by students unable to secure highly-paid and popular co-op positions, and by students placed in entry-level jobs that are unrelated to their academic programs. Second, interviews for co-op positions appear to be causing anxiety: students fear being unprepared or unqualified, especially when interviews coincide with exams. These findings suggest actionable insights for academic institutions, including managing students' expectations and ensuring that co-op interviews do not conflict with academic deadlines.

2. RELATED WORK

In the context of social media mining, the closest work to ours is that of Bagroy et al. [1], which proposed a mental well-being index for college campuses. The index was computed by measuring the fraction of a given college's Reddit discussions that were related to mental health issues, as determined by a classifier. In a related study, Saha et al. [24] computed the fraction of these discussions that was classified as hate speech, and identified expressions of stress linked to exposure to hate speech. However, these studies did not report any issues related to co-op.

Next, we review related survey-driven studies. Drysdale and McBeath [12] surveyed 1970 students about psychological attributes such as hope, procrastination, self-efficacy, and study skills. They found that co-op students had lower anx-

Mohammad S. Parsa and Lukasz Golab "Social Media Mining to Understand the Impact of Co-operative Education on Mental Health" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 653 - 657

ity, a better attitude, better use of study aids, and better time management. Drewery et al. [10] surveyed 1989 co-op students and found that students who see a strong connection between the work term and their academic program are more likely to feel satisfied and perform well. Rowe [23] surveyed 29 researchers about neglected negative aspects of co-op. Some of the reported issues were related to mental health, e.g., depression of students unable to find co-op jobs or placed in jobs that are unrelated to their academic programs, and disconnect from campus life caused by alternating work and study terms. Cormier and Drewery [6] surveyed 82 students and found that those who did not find co-op employment reported negative feelings. On a similar note, Drewery et al. [11] tested two interventions, on 74 participants, to improve unemployed co-op students' well-being: a writing exercise and information about coping with stress. The first was found to be effective, but not the second. Finally, Deziel et al. [9] surveyed 312 students about their mental health and found that it is related to academic and demographic factors such as program, year of study, and gender. However, the effect of co-op was not considered.

3. DATA AND METHODS

3.1 Data Collection and Pre-Processing

Reddit is an online social media platform divided into over 100,000 user-created discussion communities referred to as *subreddits*. A subreddit contains a number of *posts* that initiate discussions, and a post is followed by (zero or more) *comments*. Subreddit names begin with “r/” and are indicative of the content. For example, r/Fitness contains discussions of fitness and physical exercise, r/StarWars is a forum for fans of Star Wars movies, etc. As of 2019, there are over 400 million users on Reddit. Each user has a Reddit ID, but is not required to reveal any personal information.

Previous work [1] has identified the subreddits corresponding to top U.S. colleges according to U.S. News¹. We also use these subreddits in our analysis, listed in Table 1. Additionally, we collected the subreddits corresponding to top Canadian universities according to McLean’s Magazine², listed in Table 2. We downloaded these subreddits (posts and comments) from a publicly accessible database on Google Big Query³, spanning from September 2015 to September 2019. The sizes of each studied subreddit are shown in Table 1 and 2, in the “before” columns; the numbers in the “after” columns refer to content relevant to mental health and co-operative education, as determined by our filtering methods described in Section 3.2.

Next, we perform standard text pre-processing. Following previous work on Reddit data mining [17], we remove posts and comments with fewer than 256 or more than 4096 characters: short ones are unlikely to be meaningful (and may instead correspond to URLs), while long ones may mention more than one topic. We also remove stopwords and we lemmatize the remaining words (i.e., we group together all the *inflected* forms of a word) using the Python NLTK parser.

3.2 Content Filtering

Academic subreddits discuss a variety of topics related to the corresponding college, such as admissions, academics and campus events. Thus, the next step is to *filter* the data and identify discussions that are relevant to our analysis, namely those which 1) are related to mental health, and 2) are related to co-operative education.

First, we apply a *classifier* that predicts whether a post or a comment is likely to be related to mental health. We use the logistic regression classifier from Bagroy et al. [1], which was originally used to compute the percentage of discussions on academic subreddits that are related to mental health. This classifier was trained by considering all posts on the subreddit r/mentalhealth to be mental-health-related and all posts on control subreddits (among them r/food, r/technology, and the FAQ forum r/AskReddit) to be unrelated.

Next, we only retain posts and comments that appear re-

Table 2: Canadian academic subreddits: number of posts and comments before and after processing.

lated to co-op, and we do this by only keeping those which contain at least one of the following co-op related terms: “coop”, “interview”, “resume”, “workterm”, and “intern”. Note that we lemmatized the words during pre-processing, so “interview” also captures similar words such as “interviewer” or “interviewing”.

3.3 Topic Modelling

We then apply topic modelling to the posts and comments that passed the above mental health and co-op filters. First, we vectorize the comments and posts in a standard way. For each post or comment, the i th entry of its vector corresponds to the Term Frequency - Inverse Document Frequency (TF-IDF) of the i th word. We compute the TF-IDF score of a given word for a given post or comment as follows: we divide the number of times the word appears in the given post or comment (TF) by the fraction of total posts and comments that contain at least one occurrence of this word (DF). TF-IDF is frequently used when vectorizing text as it takes into account both the uniqueness of a word in the entire dataset and the importance of the word to the specific document (in our case, the specific post or comment).

Next, we run the Non-negative Matrix Factorization (NMF) topic modelling algorithm [27] on the vectorized posts and comments. NMF clusters the data into topics and produces a list of representative terms called *topic descriptors* for each topic. Each such term has a “representativeness” score, and we select the top-10 highest-scoring terms for each topic. Additionally, for each topic, we report the top-10 most frequent word n -grams (for n up to three, i.e., sequences of up to three consecutive words) within the posts or comments

belonging to the given topic.

NMF requires the number of topics as input. To select an appropriate number of topics, we ran NMF to produce between 2 and 100 topics, and computed the *coherence* [20] of each output (higher is better). We obtained the highest coherence for ten topics.

Another issue with NMF is that despite our text pre-processing, some topic descriptors were uninformative. Following prior work on topic modelling [17, 25, 2], we repeatedly remove uninformative terms from the posts and comments and re-run NMF until the topic descriptors no longer contain any uninformative terms. After two iterations, all the top-10 descriptors became informative.

Finally, we extract issues affecting students from the NMF topic descriptors, the frequent n -grams, and a manual inspection of a 5% sample of posts and comments assigned to each topic.

4. RESULTS

Table 3 shows the topic modeling results for posts and comments related to both mental health and co-op, including topic descriptors, a sample of frequent n -grams, and the percentage of content assigned to each topics. After inspecting these results, plus a sample of posts and comments assigned to each of the ten topics, we manually group the topics into issues, as shown in Table 4 (where we also point out which topics from Table 3 describe which issue).

Topics 1, 2, 4, 9 and 10 cover over 60 percent of the content and appear related to competition, specifically the competitive nature of the co-op job market. Upon manual inspection of a sample of posts and comments, we found that students express self-doubt and feelings of inadequacy when unable to secure a desirable co-op job, especially when one’s classmates and friends are able to obtain such jobs. There were also some discussions about choosing a good co-op program that enables interesting and highly-paid co-op job opportunities, concerns over not having enough experience to qualify for these desirable jobs, and the stress of maintaining a high GPA to qualify for or remain in such programs. Notably, many of the posts and comments related to competition referred to technology and software roles, as well as large technology employers such as Facebook and Google. This is likely due to the fact that co-operative programs are mainly in science and engineering.

Next, topics 3 and 5 are about questions students ask about co-op programs. This includes general questions related to admissions, and specific questions such as how to write a work report.

Topic 6 describes issues with interviews. Many posts and comments belonging to this topic referred to interviews for co-op jobs being stressful, especially because they often coincide with exams and other academic deadlines, and because interview processes for software positions may include lengthy programming tests. Students also reported feelings of uncertainty about how to prepare for interviews, how to acquire required skills, and what to expect. Additionally, some students reported anxiety after an interview while

Table 3: Topic modeling output for co-op related posts and comments

Topic descriptors	Frequent n-grams	%
1 work, time, people, like, make, want, hard, day, need, know	'work hard', 'people work', 'school work'	29.9
2 job, apply, degree, graduate, student, want, like, people, look, pay	'apply job', 'job market'	14.1

Table 4: Issues extracted from co-op related posts and comments

Topics	Issue	Description	%
1,2,4, 9,10	Competition	E.g. not qualifying for a desired co-op job	62.1
3,5	Questions	About co-op programs (e.g., seeking clarification when instructions are not clear enough)	20
6	Interviews	E.g., not knowing what to expect or how to prepare	7
7	Research opportunities	Not directly related to co-op	5.6
8	Group projects	Not directly related to co-op	5.3

waiting to find out if they have been hired.

Finally, topics 7 and 8 are not directly related to the effect of co-op on students' well-being; they instead refer mainly to research opportunities and participation in group projects during internships.

5. DISCUSSION AND CONCLUSIONS

By performing topic modelling on subreddits corresponding to U.S. and Canadian universities, we obtained the following insights into the impact of co-operative education on students' well-being.

1. **Competition** for internships, especially in the software and information technology fields, is a frequently discussed negative aspect of co-operative education. Prior work has observed that co-op unemployment can lead to mental well-being issues [6, 11]. However, our results further indicate that not securing a desirable, high-paying, challenging, and relevant employment can be a source of stress, self-doubt, and disappointment. This is especially true if one's friends and classmates are able to secure desirable jobs that are directly related their programs of study.
2. **Co-op interviews** are a source of stress for several reasons. First, students fear being unprepared or un-

qualified, especially when competing for sought-after jobs. Second, interviews often coincide with midterm examinations and other academic deadlines, meaning that students may have to choose between preparing for interviews (including preparing for programming tests) and coursework. Previous work has argued that co-operative education research should consider work-related variables in addition to education-related ones; these work-related variables include skills, job satisfaction, performance assessments, and selection interviews [23]. Our findings on co-op interviews align with this suggestion, providing data-driven evidence of another source of anxiety for co-op students.

3. As reported in previous work [23], we also found some reports of **loneliness during workterms**. Additionally, **moving and finding a place to live** during a workterm can be a source of stress.

Our findings suggest actionable insights for academic institutions and students. First, it is important to manage co-op students' expectations. For example, universities may want to offer workshops that explain the competitive nature of the co-op process and help students find jobs they qualify for. Junior students, specifically, should keep in mind that they may not immediately qualify for the sought-after positions secured by their senior colleagues. Additionally, these workshops should provide advice on interview preparation, coping with frequent moving, and finding short-term living arrangements during internships. Second, co-op interviews should not be scheduled during peak academic times. Having more time to prepare, especially for software interviews with programming tests, may reduce anxiety.

One limitation of this study is that it only reflects the opinions of students who are active on Reddit. Nevertheless, our findings can be used as a starting point for additional focused research. In future work, we plan to survey students to confirm our findings about the competitive nature of the co-op job market. Additionally, we will analyze course discussion forums to further investigate the impact of co-op interviews on class schedules and academic deadlines.

ABSTRACT

Educational traces are distinctive compared to the usual data a recurrent neural network encounters: there is a difference between two consecutive educational traces generated by a same learner if they are separated by 2 minutes or 2 months. Indeed, in the latter case, the learner who generated the trace may have forgotten the associated skill, which is less likely in the former case. Recurrent Neural Networks have seen a surge of popularity in the recent few years thanks to Deep Knowledge Tracing. While the focus has mostly been on the network architecture, we propose here a novel framework where traces are enriched with information relative to the temporality before they are used to train the network, and assess the performance on two datasets (Lalilo and ASSISTments 2012), which is not improved by this approach.

Keywords

Educational Data Mining, Neural Networks, Trace enrichment, Temporality

1. INTRODUCTION

1.1 Modelling student learning

As reminded by Choffin et al. [3], there are two main approaches to model students' learning: knowledge tracing and factor analysis.

On the one hand, knowledge tracing approaches model students' learning over time by nature by taking into account the sequential order of traces. Historically, these approaches started with Hidden Markov Models (HMMs) which were particularly used for Bayesian Knowledge Tracing (BKT) [4]. More recently, Deep Knowledge Tracing (DKT) appeared and spread partly thanks to increases in computing power [13]. The key idea is to model skills mastered by the students using Recurrent Neural Networks (RNNs).

On the other hand, Factor Analysis models have been developed since the 1950s (cf. [15] for a recent synthesis). They

rely on the idea of making explicit the factors that can have an impact on students' success on a given exercise. Training the model then consists in computing the weight of those various factors in success.

1.2 How Recurrent Neural Networks are usually used

Thanks to massive increase in GPUs computing power, research in artificial neural networks and deep learning has developed at a fast pace over the past decade [10]. In the EDM community, its first use came with DKT in 2014, which uses RNNs in order to continuously model students' learning over time. Since then, several variations of RNNs have been created to better model students learning, such as Dynamic Key-Value Memory Networks for Knowledge Tracing (DKVMN) [17] and more recently Deep Hierarchical Knowledge Tracing (DHKT) [16] and Knowledge Query Network [11]. However all those alternative models only work on trying to adapt the structure itself of the RNN.

Outside of the EDM community, today some of the main uses of RNNs include natural language translation, speech recognition and time series forecasting. Those three uses have one common point: the distance between two successive data is always the same (a single space between two words of a text, 25ms between two audio samples in speech recognition or a same time difference between two points in time series). Nonetheless, this property is usually not true on problems datasets generated by students using various learning platforms or intelligent tutoring systems (ITSs) which are commonly considered in the EDM community. Indeed, in this context two consecutive log entries could be separated by two minutes (for two exercises done during the same learning session) or two months (if the student stops using the learning platform for a while). And when this time is long, it is likely that the student has either significantly progressed on that skill (through work outside of the system, e.g. class work) or on the contrary they may have forgotten some previously mastered skills.

1.3 Beyond sequentiality: temporality

But there are reasons to think that taking into account time data can significantly improve success prediction for an exercise. The importance of modeling temporal aspects in analyses of learning has been well-established in the EDM and LAK communities [9]. In sequence mining approaches for instance, authors tend to take it into account by allowing gaps between actions [8] and/or with feature engineering

Thomas Sergent, François Bouchet and Thibault Carron "Towards Temporality-Sensitive Recurrent Neural Networks through Enriched Traces" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 658 - 661

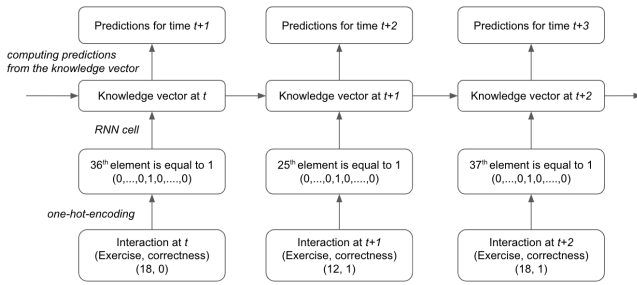

Figure 1: DKT structure. Adapted from [13]

by integrating this aspect in the actions themselves (short vs. long actions) [2]. The DAS3H model [3], which does not use RNNs, uses time windows of various durations to try to characterize the slopes of the forgetting curves for each skill. In deep learning approaches, Nagatani et al. [12] slightly modify the RNN structure to use exercise counts and time gaps between two similar exercises as additional inputs and are able to increase the AUC (Area Under ROC Curve) of predictions. In the medical field, a similar study to predict patient follow-ups benefited from a modification in the LSTM cell making it time-aware [1]. So likewise here we want to investigate ways to use the traces temporality and whether this could improve the quality of the predictions.

2. METHOD

2.1 Deep Knowledge Tracing in a nutshell

As mentioned before, the principle of DKT and its variants relies on an RNN whose weights characterize how a student's skills mastery evolves after an interaction with a learning system, such as an ITS. An interaction with the system is represented as a couple {exercise, answer}. So if there are K exercises with a boolean answer, $2K$ interactions are possible. In order to facilitate calculations in RNNs, they are usually one-hot-encoded using a binary vector of $2K$ values. For a sequence of N values, each interaction gets sequentially through the RNN. At a time t , the t -th interaction goes through the cell of the RNN thus providing the new vector representing the estimated knowledge of the student at that time. This vector can then be used to predict success on a given exercise at time $t + 1$ (cf. Figure 1). Training a RNN thus corresponds to learning the transitions between a given student's knowledge vectors. We can notice that nowhere the temporal distance (or time gap) between two inputs is considered (cf. Figure 2 top), and as far as the authors know, no knowledge tracing algorithms are currently considering it.

2.2 Our proposal

Usually, enriching the traces consists in feature engineering and tends to be presented as an alternative to Recurrent Neural Networks [6]. [12] and [1] added temporality by modifying the structure of the neural network to include temporal information. Here we try a different approach by inserting new traces in the dataset, doing meta feature-engineering to be used by a Recurring Neural Network. Our idea consists in considering all traces from students as a sequence with missing values when there are no new trace for a given period of time. In cases like this, one can usually infer the

Dataset	% of traces spaced by	
	> 7 days	> 30 days
ASSISTments12	3.1	0.6
ASSISTments17	1.1	0.4
Algebra I 2005-2006	0.3	0.02
Bridge to Algebra 2006-2007	0.02	0.003
Lalilo	2.0	0.4

Table 1: Dataset traces spread

missing values [7] by (1) adding data whose values are equal to the average of previous data or (2) adding again the same data that was last added. However, neither of these two approaches can be applied here. First, they are typically used for time series where only some variables are missing at time t but not all of them, whereas here it is equivalent to having all variables missing at time t . Moreover, averaging previous interactions does not make sense mathematically speaking. Finally, adding again the same interaction that was last added would not take into account the fact the student may have been progressing or forgetting during the time in which they were not using the learning platform.

Our proposal thus consists in adding traces (further on referred to as "artificial traces") at a regular predefined static time interval when students are not using the learning platform. The underlying hypothesis is that the RNN will be able to interpret those as time passing by. Those artificial traces are added as exercise $K + 1$ (knowing there are only K exercises initially). Thus if we add traces every month without any exercise done, after 3 months without use, 2 artificial traces will have been added (cf. Figure 2 middle). In a similar scenario, if traces are added every week without any exercise done, 11 artificial traces will have been added (cf. Figure 2 bottom).

Adding those traces results in modifying the student's knowledge vector after each exercise $K + 1$. After a given time without any new exercise done, the predictions corresponding to the probability of success will therefore differ from the ones without any artificial trace. When the RNN learns the meaning of that $K + 1$ -th exercise, it could lead to an improvement of the predictions.

In order to keep the initial tuple structure, we also add an arbitrary correctness of 0, which is not used practically to train the network.

3. EXPERIMENTS

3.1 Experimental setting

We computed the number of traces spaced by more than 7 and 30 days in a number of classical datasets : ASSISTments12 [5], ASSISTments17, Algebra I 2005-2006 and Bridge to Algebra 2006-2007. The two latter datasets stem from the KDD Cup 2010 EDM Challenge [14]. We were also able to get a dataset from Lalilo which is a web-app fostering literacy for K-2 (Table 1). In order to evaluate the performance of the traces enrichment, we have trained DKT and DHKT algorithms on the two datasets that had the highest spread in traces: ASSISTments12 (assist12) and Lalilo. Their main characteristics are summarized in Table 2.

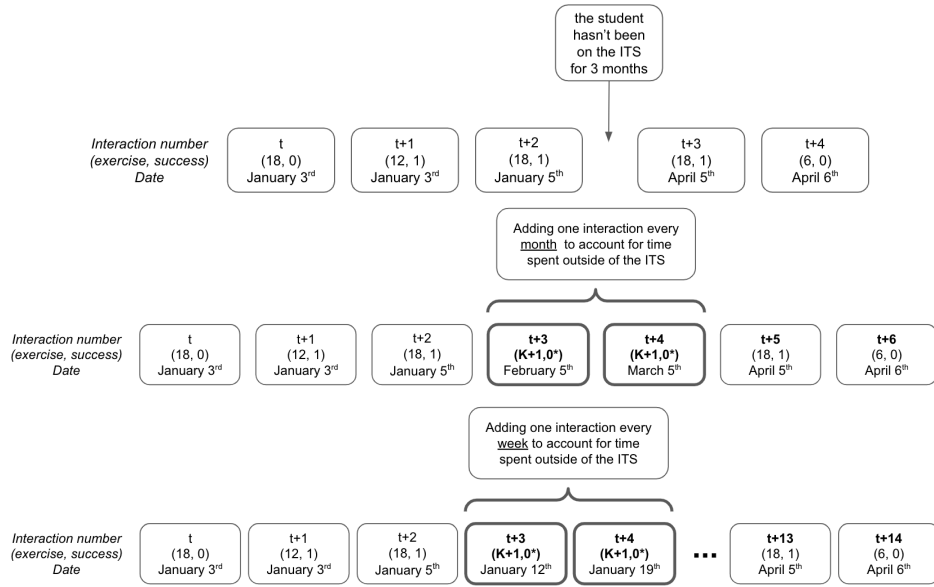

Figure 2: Traces fed to the network before enrichment (top), after *monthly* temporal enrichment (middle), or after *weekly* temporal enrichment (bottom)

Dataset	Users	Items	Skills	Interactions	Median length
lalilo	58,585	3,439	16	4,418,190	46
assist12	29,018	53,086	265	2,711,602	49

Table 2: Datasets characteristics

A key question with our approach relates to the frequency of use to add artificial traces. Indeed if the frequency is too high, it is likely that the artificial traces would disturb the RNN learning. Conversely, if the frequency is too low, it won't capture precisely the elapsed time. Therefore we compared the impact of various frequencies of artificial traces addition.

Our models have been implemented in Python and PyTorch for the Deep Learning aspects and the corresponding code is available online on GitHub¹. Following Choffin et al. [3], we removed users for whom the number of interactions was less than 10 and interactions with NaN skills. We randomly sample randomly training (80%) and testing (20%) sets and give results on the testing set. We average on five different seeds and give standard deviation.

3.2 Results and analysis

A synthesis of the results can be found in the Tables 3 and 4. We use AUC to evaluate the performance of the models. No significant improvement in the predictions appear, and even with a high frequency of added artificial traces (daily), there is no significant degradation either. Several hypothesis could explain this lack of impact. It is possible that in those datasets, students are not progressing or regressing significantly between two moments when they use ASSISTments. A lack of differences would also be likely to be observed if long gaps without usage are unlikely. For example, if most

DHKT	None	0.771 (0.002)
DHKT	1	0.770 (0.002)
DHKT	7	0.771 (0.005)
DHKT	14	0.771 (0.003)
DHKT	30	0.770 (0.002)

Table 3: Performance comparison on the ASSISTments12 dataset

students do 50 exercises over a few days, then stop using the system for 2 months, and use it again intensively for a week, the only exercises impacted would be the ones right after the gap of two months, i.e. only a small percentage of exercises overall. It is thus also possible that other datasets would be more sensitive to measure the impact of this artificial traces addition.

4. CONCLUSION AND PERSPECTIVES

We proposed here a framework to enrich learning traces to train recurrent neural networks. This enrichment which consists in adding artificial traces allows to add a temporality aspect into traces which normally only take into account se-

Model	Added trace frequency (# days)	AUC (std dev)

DHKT	30	0.700 (0.001)

Table 4: Performance comparison on the Lalilo dataset

quentiality. Unfortunately, ASSISTments 2012 and Lalilo datasets did not allow us to reveal a significant impact of our approach, but we have reasons to believe these particular datasets were not the most appropriate to measure a significant difference in the performance of prediction. Our future works thus involve (1) focusing on a population of students who has a scarce use of a learning platform over a large period of time (several months or years), (2) focusing on the impact of this algorithm over prediction specifically on exercises done right after a large time gap (during which the student may have learned or forgotten things), and (3) identifying learning platforms that teaches skills that are maybe easier to forget over time (e.g. vocabulary in a foreign language), or finding already existing datasets coming from such a platform.

5. ACKNOWLEDGMENTS

We would like to thank the reviewers for their thoughtful comments and efforts towards improving our paper. This work is funded by Lalilo.

Lauren.N.Singelmann@ndsu.edu

ABSTRACT

In order to keep up with the rising demand for new and innovative solutions in an evolving world, an even greater importance is being placed on training engineers that can tackle big problems. However, the process of teaching engineering students to be innovative is not straightforward. There are multiple ways to demonstrate innovation and problem-solving abilities, meaning traditional educational data mining methods aren't always appropriate. To better understand the process of problem-solving and innovation, this work collected data from students working on innovation projects within a course and determined appropriate ways to gain information and insight from the data. Students wrote and categorized learning objectives in an online portal, which generated log data when they created, updated, and completed personal learning objectives and corresponding deliverables. Classification models that were both robust (ROC AUC > .95) and interpretable were applied to both the language used in the objectives and the quantifiable features such as number of objectives, time of completing certain milestones, and number of deletions and edits. By extracting the most significant features, we are able to see which variables are most likely to lead to student success in innovation-based learning. This would aid instructors in offering impactful support to students or eventually lead to an online tutoring system. The conducted analysis will help students develop and grow throughout the innovation process in this course or in other open-ended problem-solving environments.

Keywords

Classification, open-ended learning, innovation, problem-solving

1. INTRODUCTION

Thomas Friedman describes the current era as the *Age of Accelerations*, the time at which technology, the climate, and globalization are all evolving at a rate like we've never seen before [5]. As these areas progress, engineers need to be

able to identify and solve problems more quickly and effectively than ever before. ABET [1], the National Academies of Engineering [10], and experts in both engineering and education [12] all stress the growing importance for training engineers that can use their problem-solving skills to create new and innovative solutions. This work explores how students work on these skills and solve real-world problems in an Innovation-Based Learning (IBL) course. IBL students apply their content knowledge and skills to work on a real-world project with the goal of creating value external to the class. For example, successful students have presented their work at conferences, published papers, participated in invited outreach activities, or submitted invention disclosures. Students are required to write their own learning objectives and show evidence of work. However, because there are so many possible approaches to the course, predicting and understanding student success can be challenging.

In order to better understand what makes students successful in this type of course, data were collected from the online learning portal from the class. Because of the open-ended nature of the course, classification and knowledge discovery can be challenging. We wanted to build classifier models that were robust, but also interpretable in order to better predict and support future students in IBL-style courses. Therefore, three main research questions were explored:

RQ1: What feature sets and models work best for IBL data?

RQ2: How early can student success be predicted?

RQ3: What features are most likely to differentiate between top-performers and lower-performers?

Finding answers to all of these questions can help guide instruction in the course and potential development of an online tutoring system for innovation-based learning courses and other open-ended problem-solving environments. This paper will present literature about open-ended learning environments, give details about the course and data collected, elaborate on how the research questions will be tested, and share results and takeaways.

2. OPEN-ENDED LEARNING

Open-ended learning is a pedagogical approach that allows students to use their own motivations and approach to learn about the world [8]. Students are taking part in authentic problem-solving, practicing metacognition, and creating unique pathways through their learning. Examples of open-ended learning environments include computer pro-

Lauren Singelmann, Enrique Alvarez, Ellen Swartz, Ryan Striker, Mary Pearson and Dan Ewert "Predicting and Understanding Success in an Innovation-Based Learning Course" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 662 - 666

programming exercises, project-based learning, and inquiry-based learning. Educational research exists about the potential benefits of these experiences [11], but there are still gaps in understanding about how students progress through open-ended learning environments. Educational data mining (EDM) has shown great potential in being able to help shed light on student trajectories and habits within open-ended learning environments [20].

EDM has shown preliminary successes in open-ended learning environments such as learning computer programming [9], project-based learning courses [17], online tutoring platforms [3,4], learning-by-teaching platforms [6], and language tutoring systems [13]. Continuing to make strides in understanding learning in open-ended environments is imperative because it will be an important step in implementing evidence-based practices and assessment in these environments.

3. METHODS

3.1 Cardiovascular Engineering Course

Data were collected from an upper level cardiovascular engineering course at a medium-sized research university. Students learned about the main concepts of cardiovascular engineering including functional block diagrams of the heart, arterial systems, and ECG. The students were assessed on their ability to apply these concepts to a project they worked on during the semester. After identifying a project and a team, they wrote learning objectives and corresponding deliverables that would share what they needed to learn, when they would learn it, and how they would demonstrate it. Students could adjust their learning goals as needed, but they were expected to share their progress on their project multiple times during the semester [14]. To get an A in the course, students needed to work on an innovation project and achieve high external value. High external value is demonstrated by sharing your work outside the course and getting review from a subject-matter expert, e.g. publishing a paper, presenting at a conference, or submitting an invention disclosure [2,19].

3.2 Online Learning Portal

A custom online learning management system (LMS) was created for students to keep track of their learning objectives and deliverables [18]. When students add a learning objective, they give it a title, description, assign it to a level of Bloom's Revised 3D Taxonomy [7], and categorize it using the list of objective categories in Appendix A. When adding a deliverable, students give it a title, description, level of external value, estimated completion time, and status (not started, in progress, or completed). An example of a learning objective and corresponding deliverables is shown in Figure 1. Every time a student adds, edits, or deletes an objective or deliverable, the action is recorded as a log entry, allowing us to see not only the completed products, but also early iterations of the students' objectives [16].

3.3 Data Set

28 students agreed to share their data during the semester. The average student logged approximately 8 objectives, 32 deliverables, and visited the platform more than 65 times during the semester. 17 students achieved high external

Figure 1: Example of collected learning objective and corresponding deliverables.

value, 10 students worked on an innovation project but did not achieve high external value, and 1 student made some learning goals but did not complete any.

3.4 Feature Collection

Two main types of features were used and compared: quantitative data and text data. The quantitative features that were extracted from the data include countable features (e.g. number of planned learning objectives, number of logins, etc.), quarter-based progress (e.g. number of deliverables completed during quarter 2, number of learning objectives deleted during quarter 4, etc.), presence of the specific learning objectives as seed in Appendix A (e.g. presence of *Invention Disclosure* objective, number of *Fundamentals of Research* objectives, etc.), and the level of learning as defined by Bloom's Revised Taxonomy and the level of external value.

For the text data, all learning objective and deliverable titles and descriptions were extracted for each student. Using the scikit-learn library in Python, all the words that students wrote in their objectives and deliverables were tokenized, counted, and scaled.

4. EXPERIMENTS

4.1 Models and Feature Sets

In order to predict which students would achieve high external value during the course of the semester, three classifier models were tested: Support Vector Machine (SVM), Logistic Regression (LR), and K-Nearest Neighbors (KNN). These three models were chosen because they have some level of interpretability, an important feature in EDM [15]. In order for instructors to use the discovered information, they need to be able to understand where it was derived from. The baseline model was a Majority Class (MC) classifier.

In addition to comparing the models, both the text and quantitative features were compared. For each set, we also compared using all features to using the top K features. K was optimized and set at 24 for text and 15 for quantitative.

4.2 Evaluation Metrics

Each model was evaluated by calculating accuracy, recall, F1 score, and Area Under Receiver Operating Characteristic Curve (AUC). Accuracy is the proportion of correctly

classified students to all students. Recall is the proportion of students that the model identified as not being on track to success to the number of total students that did not achieve high external value during the course. F1 score is a performance metric that takes the harmonic mean of precision and recall. AUC is the area under the Receiver Operating Characteristic (ROC) curve which shows how well the model can differentiate between the two classes. All models were evaluated using ten-fold cross validation.

4.3 Trajectory

In addition to exploring models that were developed by using each student's final learning objectives and deliverables, we were also able to explore how prediction power of the models changed during the course of the semester. Models were created using daily snapshots of all students to see when the model can begin predicting student success.

5. RESULTS

5.1 Comparing Models and Feature Sets

Table 2 shows the accuracy, recall, F1 score, and AUC for each of the models and feature sets explored. These classifiers used all available data during the semester. Almost all models performed better than the MC baseline test. The text features consistently performed better than the quantitative features, and using feature selection usually improved the model as well. The top models are SVM and LR, both using the top 24 text features. In addition to having low performance, the quantitative models are also difficult to assess in real time. The most relevant features of the quantitative models can give us some information, but they are not as helpful when making predictions. Therefore, we'll focus on using the text models moving forward.

Feature Type	Model	Accuracy	Recall	F1	AUC
Baseline	MC	.6	-	-	.5
All Text Features	SVM	.783	.85	.758	.831
	LR	.883	.85	.866	.972
	KNN	.583	.95	.533	.700
Top 24 Text Features	SVM	.917	.85	.9	.937
	LR	.917	.85	.9	.952
	KNN	.783	.85	.767	.832
All Quantitative Features	SVM	.7	.6	.648	.704
	LR	.717	.5	.612	.697
	KNN	.567	.7	.482	.523
Top 14 Quantitative Features	SVM	.667	.5	.563	.851
	LR	.7	.5	.597	.798
	KNN	.667	.9	.615	.65

Table 1: Performance metrics for each of the models using end of semester data

5.2 Exploring Model Trajectory

Because the model performs well at the midpoint in the semester, the next experiment explored at what point in the semester top-performers can be differentiated from lower-performers. All models used the 24 top text features. Figures 2 and 3 show the accuracy and AUC of the models over time, respectively. The SVM and LR models improve as the

semester goes on, with the AUC for the models leveling out at about day 55. Therefore, the midpoint of the semester seems to be an appropriate time to use the model, but using it earlier might give mixed results.

Figure 2: Accuracy of the text-based models over time compared with the baseline MC classifier

Figure 3: AUC of the text-based models over time compared with the baseline MC classifier

5.3 Knowledge Discovery

In order to better understand what features are most significant in predicting success, the most important features were extracted. By using linear classifier models instead of black-box models like neural networks and other deep-learning models, Chi-Square and the weights of each feature could be calculated. Chi-Square tells us which features are not independent of their classification, meaning they are more likely to differentiate between classes. The greater the Chi-Square value, the greater dependence on classification, meaning that feature is a strong differentiator. Weight can tell us which class a feature is more likely to be found in.

Figure 4 shows the 24 features with the largest Chi-Square value. If the word was more likely to be found in a low-performing student, the Chi-Square value was multiplied by -1 to allow for easier interpretation. The top words that differentiated low-performing students were *information*, *presentation*, *engineering*, *website*, *loops*, *review*, and *feedback*. The top words that differentiated high-performing students were *sensor*, *signal*, *model*, *device*, *idea*, and *symposium*.

Figure 4: The Top 24 text features that differentiated the most between successful and unsuccessful students. Words with positive Chi-Square values were more associated with successful students. Words with negative Chi-Square values were more associated with unsuccessful students.

Table 4 shows the quantitative features that had the highest Chi-Square values. The weights were used to know which group the variable was more likely to be present in. Top students were more likely to have data analysis, data collection, journal manuscripts, and general Mechanisms of Research learning objectives. Unsuccessful students were more likely to have providing critique and outreach communication learning objectives.

Variable	Chi-Square	Group
Presence of MR4: Data analysis	3.882	Successful
Presence of RM3: Providing critique	3.091	Unsuccessful
Total number of Mechanisms of Research Learning Objectives	2.146	Successful
Presence of MR3: Data collection	1.941	Successful
Presence of PC5: Journal manuscript	1.941	Successful
Presence of PC7: Outreach communication	1.807	Unsuccessful

Table 2: Quantitative features with the highest Chi-Square values

6. DISCUSSION

6.1 Insights Gained

Unsurprisingly, top students were more likely to mention work on their abstracts, posters, pitches, and presence at the BME Symposium (an on-campus biomedical engineering conference). Low-performing students were more likely to have deliverables like websites and outreach activities. Although websites could be high impact deliverables, they can also just be a report of students' lower-level learning. For outreach activities, this can be interpreted broadly and could be outreach to a classmate or small group rather than a visit of high impact. In addition, successful students were more likely to have words related to the design process such as *idea*, *develop*, and *data*. Unsuccessful students were more likely to mention words like *information*, *presentations*, *review*, and *feedback*. We believe these words appeared in low-level students because they were activities required by the class. Therefore, top students did not see the need to write specific learning objectives about them, but lower performing students added them in an attempt to have more items logged.

6.2 Limitations

Just as the world around us is accelerating, so are our students. Therefore, these models will need to continue to evolve and improve as students change their approach to the class. Aiming for consistently high performing models is not a realistic goal for this work. Rather, we can use the knowledge discovery from these models to better understand how students move through these environments and aim to better support them.

6.3 Future Work

In addition to collecting data during more semesters and at more universities, we would also like to explore both clustering and sequential modeling moving forward. By clustering similar students and finding patterns that emerge in successful students in that cluster, we can give personalized feedback that allows students to find success while staying true to their own learning goals.

7. CONCLUSION

Modeling student learning in open-ended learning environments can be challenging, but SVM classifiers show potential in being able to predict which students will be successful in an IBL course. Models had accuracy of over 80% and AUC of over .95 by the midpoint in the semester. This accuracy increased to over 90% by the last few weeks of the semester. By using linear models, we could also gain insight as to what features differentiated between successful and unsuccessful students. Using these results can help instructors know which students could use extra support and lead to more understanding about how students progress through problem-solving environments in general. By understanding how to better support our students in the innovation process, we can foster the next generation of problem-solvers to take on the *Age of Accelerations*.

Linguistic Changes across Different User Roles in Online Learning Environment. What do they tell us?

Lavendini Sivaneasharajah, Katrina Falkner, Thushari Atapattu

The University of Adelaide

{lavendini.sivaneasharajah, katrina.falkner, thushari.atapattu}@adelaide.edu.au

ABSTRACT

In recent years, we have witnessed an increasing interest in online learning environments, particularly in Massive Open Online Courses (MOOCs). However, prevailing studies show that lower percentage of students complete their courses successfully in online learning environment. The vast amount of student data available in MOOC platforms enables us to gain insight into student learning behaviours. In this paper, we explore the idea of ‘student roles’, identifying linguistic change associated with roles that will later help us to understand students’ learning process in MOOCs. As an initial stage of this research, the study aims to categorise student roles (e.g. information seeker, information giver) using discourse analysis, and to further analyse the linguistic change for each student role with time. A multi-class classifier has been built to identify user roles with 82.20% F-measure. Further, our study on linguistic changes demonstrates that distinctive behaviors can be observed across different user roles. Prominent observations include discourse complexity, lexical diversity, level of information embeddedness and lexical frequency profile being high in information giver in comparison to information seeker and other user roles.

Keywords

MOOCs, Discussion forums, Student Role, Natural Language Processing, Machine Learning

1. INTRODUCTION

With the advent of Massive Open Online Courses (MOOCs) there has been an eruption in learning environment [10]. Students are increasingly seeking alternative learning mediums, with MOOCs increasingly looked upon as a valuable source of learning. As many of the MOOCs are freely available for students, it draws interest of thousands of learners.

According to the statistics, over 101 million learners are globally registered to study using MOOCs by the year of 2018 [16]. However, studies show that only one in every twenty students who enrol in MOOCs complete their studies successfully [9]. The participation in MOOCs seems complex with students’ enrolment for varying purposes and varying

intentions [17]. Completion is not necessarily the only indicator of learning success. Knowing that students may enroll to courses for other purposes, we need to explore other perspectives of learning success beyond completion.

The primary problem aims to solve by this research is whether analysing the student role and its associated linguistic change can be used to understand student learning. We believe learner role can give us an indication on whether learning gain is important to measure learning success. We try to answer “Moving between roles is potentially an indication of learning gain”. This hypothesis has not been explored yet in prevailing literature.

As the studies discuss in this paper demonstrate a proof of concept, our initial stage is to identify user roles and a sample of linguistic indicators that are associated with these roles. Our overarching goal is to track these roles and their associated linguistic changes with time. And eventually, predicting the grades for student using these discourse features. We assume observing these roles and associated linguistic changes will eventually result in a deeper understanding of the student’s learning lifecycle.

Hecking et al. [5] identifies these roles with both linguistic and community-related features (e.g. votes, views). However, in a real time system, it is not realistic to wait for the community-related features to classify students into different roles as structural features can be generated throughout the course and they may change with time. Therefore, we intend to identify student roles in MOOC discussion forums solely based on a discourse analysis.

Few research studies [3; 4] have focused on linguistic changes that occur in online communities. Yet, linguistic changes have not been studied along with students’ role.

With reference to the aforementioned aspects, we aim to answer the following research questions: RQ1: Can we build a model that could predict user roles (information seeking, information giving, other) using linguistic only features? RQ2: Do linguistic indicators change significantly across user roles?

Answering these questions will result in identifying user roles and its associated linguistic changes in discussion forums. These studies may assist to understand students’ learning in online learning environment.

The contribution of this work includes a multi-class classification model that uses linguistic-only features to predict user roles in MOOC discussion forums. Since it uses linguistic-only features, our model can be applied to any online forums (e.g. technical forums) for role prediction. Further, we examine the linguistic indicators and its changing patterns associated with user roles at this stage with the intention of proposing a framework in future to understand students’ learning.

Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 667 - 671

2. RELATED WORK

2.1 User role/ Post classification

Searle's taxonomy [15] has been widely used in literature and proven to be a most successful method in speech act classification. From this point, several classification mechanisms have been evolved based on Searle's taxonomy [1; 7].

Hecking et al. [5] have carried out post classification by integrating the categories that prevail in the existing research studies. The study presents three classes (information seeking, information giving and other). It used content-related features (e.g. phrases – “need help or helps you”) and contextual features (e.g. position in the thread, number of votes) for classification purposes and obtained an average of 70% accuracy.

In a real time system, it is not realistic to wait for the contextual features to predict the given classes as they occur throughout the course and changes with time. Therefore, our study focuses solely on the linguistic aspects over contextual and structural features.

2.2 Linguistic change in online communities

An important facet of linguistic research is to identify the correlation between user lifespan and their language use [3; 13]. Given the rich recent work on linguistic analysis in different online communities [3; 6; 13; 14], research scholars also have attempted linguistic analysis in MOOC. Dowell et al. [4] have conducted a study on MOOC data to identify the conversion in learner's language and discourse characteristic with time. However, the research did not investigate the linguistic changes associated with each user role. To address this gap, we conducted several experiments using different linguistic features to discover discourse complexity, lexical diversity, number of embedded information and lexical frequency profile. Even though preliminary work on linguistic change has been conducted in other online communities, there is a lack of work conducted in MOOCs.

3. METHODOLOGY

3.1 Data set

We extracted a dataset from the AdelaideX¹ ‘Introduction to Project Management’ and ‘Risk Management for Projects’ courses offered in 2016 and 2017 respectively. A total of 9,497 user posts was extracted from 923 different users. We sampled 6000 posts from ‘Project Management’ for this study. We extracted user posts of students who have posted a minimum of six posts during the entire semester. Posts were manually annotated as information seeker (IS), information giver (IG) and other (O) user roles by two independent human evaluators. According to Cohens kappa, the high inter-rater agreement ($k=0.924$) between the two annotators ensures the validity of the human annotation.

User role identification

We adopted machine learning techniques to build a multi-class classifier to predict user roles (IG, IS and O) for a given forum post using discourse features and linguistic features that were extracted using Linguistic Inquiry and Word Count (LIWC)

tool². We extracted multiple features to reflect several facets of the text.

We implemented multi-class classifiers using weka for role identification. All classifiers were tested using 10 Fold Cross-Validation to assess effectiveness.

The imbalanced data were handled using Synthetic Minority Oversampling TEchnique (SMOTE). Here we split the data into 70% for training and validation and 30% for testing. Then, we oversample the minority class on each training fold during cross validation. Then, validated the classifier on the remaining fold.

On the other hand, we also performed further analysis on role classification to explore the potential techniques that can be used to address this problem. We implemented multi-class text classification using Keras, a high-level neural network API.

We used existing pre-trained GloVe word embedding to convert the user posts to 100 dimension vectors. Then, built the model with one input layer, one embedding layer and one Long Short-Term Memory (LSTM) layer with 128 neuros and one output layer with three neurons.

3.2 Linguistic study

In our second study, we conducted several linguistic experiments (e.g. discourse complexity, lexical diversity) to understand the linguistic changes of each user role with time.

3.2.1 Discourse Complexity

According to an existing study by Crossley et al. [2], discourse complexity can be measured by several linguistic indicators. One possible way is using any given reading level measures. Therefore, we used Flesch Kincaid [8], a reading level measure and used this measure to explore discourse complexity with time for each user. We also analysed the association between discourse complexity and student roles.

3.2.2 Lexical Diversity

We calculated lexical diversity to measure the vocabulary usage in the given user posts. Measuring the level of lexical diversity requires to quantify how often different kind of words are used in text. According to the prevailing literature [12], lexical diversity can be measured using different formulas such as type-token ration (TTR), measure of textual lexical diversity (MTLD), vocd-D and many. Due to flaws in the traditional methods, we chose MTLD over other lexical diversity measures as MTLD avoids the adverse effects on text length in measuring the lexical diversity.

3.2.3 Lexical Frequency Profile

We have examined the Lexical Frequency Profile (LFP) associated with each user role to understand how well user has written his discourse. Initially, we extracted n-grams from lecture transcripts. We used CountVectorizer to tokenise the text and built a vocabulary list for lecture transcripts.

We created Lexical Frequency Profile for each user post with respect to the given vocabulary list using spaCy³, an advanced Natural Language Processing API. We created a Phrase Matcher Object and applied the matcher object on each user post to

¹ <https://www.edx.org/school/adelaideX>

² <https://liwc.wpengine.com/>

³ <https://spacy.io/>

extract the keywords. Finally, we examined LFP for user roles and its pattern during a role change.

Since these linguistic indicators are normally distributed, we performed One-Way ANOVA to compare the mean value for each variable's distribution. These linguistic indicators are examined during role changes to understand whether there is a significant difference between user roles.

3.2.4 Information Embeddedness

Information embeddedness is one of the key elements that contributes towards student learning. In our study, information embeddedness can be defined as the number of information that can be extracted from any given discourse. This study attempts to find the level of information embeddedness using clause extraction.

Clause extraction has been used in a previous study [11] to determine the relationship between the clauses per sentence and language development. We develop a novel approach in which clauses are been extracted from parse tree using a rule-based approach.

Initially, a pipeline is being built with Part-Of-Speech (POS) tagging, lemmatisation using Stanford CoreNLP⁴ to get the basic interpretation of a student post. Tree Annotation is used to extract a parse tree for a given sentence. Here, we divided a student's post into multiple sentences and identified the number of clauses embedded in each sentence. Initially, clause-level tags (e.g. SBAR) and word-level coordinating conjunction (e.g. CC) have been extracted from the parse tree. Then, we implemented a rule-based approach to extract the number of clauses.

4. Results

The experiment on role identification addresses information seeking, information giving and other role classification solely based on discourse analysis. We analysed the features extracted from LIWC. Further, we performed feature selection technique known as Recursive Feature Elimination with Cross Validation (RFECV) for feature ranking. We performed the feature ranking on 1200 user posts obtained from Risk Management course. According to the RFECV sixteen optimal number of features have been selected. We retrieved the features with highest ranking and fed these features to the classifier.

We conducted Multivariate Analysis of Variance (MANOVA) to measure the significance between linguistic features and user roles. Table 1 presents the top five variables that exhibit the largest effects size along with multivariate F value (Wilks' λ).

Table 1: MANOVA analysis of language variables

Feature	F	η^2
Words per Sentence	754.853*	0.201
Question Mark	505.057*	0.144
Article	493.305*	0.141
Interrogatives	385.516*	0.114
Personal pronouns	294.884*	0.090

*p<0.001

⁴ <https://stanfordnlp.github.io/CoreNLP/>

We implemented multiclass classifiers with different sets of algorithms using Weka. All these classifiers were tested using 10 Fold Cross-Validation to assess the accuracy. Among these, the Random Forest classification model performed best with 82.20 of F measure (see Table 2). Table 2 reports the accuracy, precision, recall and F-measures for different set of classifiers.

Table 2: Results of classifier performance

Classifiers	Accuracy	Precision	Recall	F1	Cohen's Kappa
Naïve Bayes	71.28	74.40	71.30	71.00	0.5117
Random Forest	82.17	82.30	82.20	82.20	0.6955
Simple Logistic	79.35	79.60	79.40	79.40	0.6473
Logistic	79.43	79.70	79.40	79.50	0.6498
SMO	74.80	76.50	74.80	75.30	0.5770

We also performed, the text classification with Keras. As stated above we used GloVe 100 dimension vector to create the vector space for each user posts. We obtained 88.06 as test accuracy. We halt the model from further training to avoid over fitting.

The experiment on linguistic analysis uses different indicators to address the linguistic change associated with each user role.

According to the reading level measures (discourse complexity), the results indicates that if a particular user role can be seen in consecutive posts the level of complexity increases/decreases with minimum change and when there is a role change (e.g. IS \rightarrow IG or IG \rightarrow IS or O \rightarrow IG) there is a dramatic change in discourse complexity. This trend is observed across our data set.

The mean value of Flesch Kincaid Grade Level measure for user roles are as follows: $\mu = 16.15 \pm 12.86$ (IG), $\mu = 8.77 \pm 7.43$ (IS) and $\mu = 5.30 \pm 6.99$ (O). High Flesch Kincaid score indicates the discourse is difficult to understand. This implies that discourse complexity decreases along with these user role changes whereas the readability of the text becomes easier with these role changes. The results from the One-Way ANOVA test show that there is a significant difference in mean values (discourse complexity) with p-value<0.001 among these user roles.

As stated above, lexical diversity of user posts were obtained via calculating 'Measure of Textual Lexical Diversity'. The mean value of MTLT for user roles are: $\mu = 60.845 \pm 32.380$ (IG), $\mu = 52.18 \pm 39.59$ (IS) and $\mu = 34.46 \pm 46.55$ (O). This indicates that lexical diversity of the user roles are decreasing along these role changes.

The results of Lexical Frequency Profile show that the number of lecture related keywords used in user post changes during a role change. For a given user, the number of keywords used in an information giving post increases – reach an optimal number and decreases with time whereas for an information seeking post it increases/decrease with time. Moreover, information giver uses more keywords from the lecture transcript than information seeker and other.

In information embeddedness factor, we extracted the clauses using a rule-based approach. Once the number of clauses been extracted using clause-level tags and rule-based approach, we compared them with user roles (IG, IS, O). Figure 1 shows the level of information embeddedness in a user posts (number of clause) changes with time for sample of three users.

Figure 1: Information embeddedness across user roles with time

5. DISCUSSION

5.1 Can we build a model that could predict user roles using linguistic only features?

In the existing literature [5], user roles have been predicted based on the other contextual features (e.g. votes, views) which delays the predictions in a real time MOOC environment. Therefore, this study extends the line of research to construct a machine learning model to identify user roles (IS/IG/O) using linguistic-only features.

To address RQ1, we conducted an experiment on IS/IG/O post classification. The success of our approach with 82.20% of F-measure and the text analysis performed using Keras with 88.06 accuracy demonstrates that simple linguistic features can be used in role predictions in real time.

According to the feature space used in this classification, it is evident that sixteen identified linguistic features (see Table 1- we presented the first five features that holds largest effects size due to the page limit) can distinguish IG, IS, O posts. For example, information-seeking posts contain high amount of negative emotions comparatively to information giving posts. Likewise, the number of question marks is high in information seeking posts compared to information giving user posts.

5.2 Do linguistic indicators change significantly across user roles?

To investigate RQ2, we conducted several linguistic experiments to explore the linguistic change across user roles.

The results of our linguistic experiments demonstrate that the readability level (μ of Flesch Kincaid Grade Level) of the information giver is high (i.e. discourse complexity is high) when compared to information seeker and other user roles. This implies that there is a high dramatic change in the linguistic complexity during a role change. One possible reason can be information givers tend to include words that are more complex

and provide extensive information when comparing to other user roles.

We further analysed this results by manually analyzing random user posts retrieved from the data set. According to the sample user posts given below, information givers try to elaborate their information with more complex words than information seeker.

Information Giver- "Great use of the likelihood/impact scale! You might also want to use the PESTLE framework to identify broader areas of potential concern..."

Information Seeker- "That was great can i please gain form you, the Challenges you faced during you first project"

Similarly, the results obtained for lexical complexity shows that lexical complexity is higher for information giver. According to the above sample user posts, it is vital that the vocabulary usage is higher in information giver than information seeker.

The trend in the lexical frequency profile shows that information giver uses more keywords from lecture transcripts at the beginning of the course, reaches an optimal point and decreasing afterwards. One possible reason could be that they are enthusiastic to share the lecture related information during the start of the course and it increases with time. Further, the reason to decrease the amount of content-related keywords from the lecture transcript at the end of the course might be because they elaborate concepts in their own words or uses related keywords from other resources as they progress.

We can observe two kind of trends in information seeker. First trend is they use more keywords as they progress. The reason could be, they might not know the content at the beginning but with time, they know the course related keywords. Other trend is they use less keywords with time. The reason might be they try to change their role from the information seeker. Further, we hope to do a meticulous analysis to explore these patterns with the intention of discovering the exact reasons behind them.

In summary, we have achieved the aim of our study as the classifications is purely built upon the idea of utilising linguistic-only features. Further, to understand student learning, we explored RQ2 by examining the different linguistic indicators. These linguistic indicators will have a great potential to understand a user's behavior in any kind of discussion forum.

6. CONCLUSION

We have presented a multi-class user role classification in MOOC discussion forums using linguistic-only features with the intention of eliminating the drawbacks (e.g. contextual features) that exist in previous studies. Our model performed well comparing to base line model with 82.20% of F-measure

On the other hand, our linguistic study gives us a clear differentiation on linguistics aspects associated with each role. The level of information embeddedness, and discourse complexity and lexical diversity of information giver is high compared to information seeker and other. As a proof of concept, our technique demonstrated the potential of identifying the linguistic behaviors for each user role.

This novel approach holds a great promise for user role classification and the associated linguistic behavior in MOOC discussion forums. Additionally, we believe that tracking these role changes and associated linguistic changes will help to understand the student learning in MOOC discussion forums.

ABSTRACT

Eye gaze movements analysis are being increasingly used in many researches within learning context. Most of those researches analyses the eye movements fixations inside some areas of interest, the saccades trajectory and the scanpath. The eye gaze data are spatiotemporal sequences representing the dynamic of the eye fixations in the visual space over the time. In addition, they contain noises caused by different factors. The task of developing predictive model based on those raw spatiotemporal eye gazes' sequences is challenging. In this research, we present machine learning approaches that we have successfully used to address those challenges with high accuracy mainly with the deep convolutional LSTM architecture.

Keywords

Eye tracking; Deep learning; Spatiotemporal eye gazes sequences classification

1. INTRODUCTION

In some medical field such as anesthesiology, the visual perception is just a tip of the iceberg known as the "situational awareness." In fact, the clinician needs to develop the skills to see adequately the patient vital signs evolution over the time in order to build their understanding and interpretation of the clinical situation to perform their clinical reasoning. In this paper, we explore the following question: Can we tell novice and expert clinicians apart by analyzing only their eye-gaze movements to perform their clinical reasoning? Eye gaze data often contains noise which can be caused by many factors [10]. In addition, the consecutive data points generated by the eye movements trajectory over

the time within the area of interest are spatiotemporal considering their order and their positions in the visual space. Ultimately, our experiments aim to understand key differences between novice and expert clinicians eye movements behavior during their clinical reasoning. Taken together, they will provide us insights to build an Intelligent Tutoring System (ITS) aiming to reinforce gradually the learning curve of novice clinicians with some cues from the experts behavioral implicit knowledge in terms of visual attention to perform a clinical reasoning in critical anesthesiology case.

2. RELATED WORKS

The researches using eye-tracking and ITS can be summaries in two main axes according to Conati et al [6]. The first axe is the investigation of eye-tracking data as source of information for student modelling and personalized instructions. The second axe is leveraging the gaze data to attempt to understand relevant student behaviors. For that purpose, data mining techniques are often used to retrieve similarities, differences, etc. using the eye movements characteristics such as the fixations, the saccades and the scanpaths. Some researches also focus on mining eye-tracking patterns [18]. As a contribution, in this paper we propose predictive models using the sequence of the eye fixations positions over the time. These model will be used by the envisaged ITS to proactively classify eye fixations patterns as Novice vs Expert behavior in order to provide adequate eye movement tutoring services.

3. EXPERIMENTS AND DATASET

3.1 Experiments

An experiment has been conducted to collect eye gaze data for the research using an authentic task involving visual perception and clinical reasoning. Seven Novices and seven experts clinicians were asked to visualize a simulated clinical scenario to perform their clinical reasoning. A [Novice] is a resident clinician within the first or second year of the residency program (PGY1 or PGY2).¹ An [Expert] is a hospital staff member with more than 8 years experience. Each

¹PGY refers to a North American scheme denoting the progress of postgraduates in their residency programs.

Komi Sodoke, Roger Nkambou, Aude Dufresne and Issam Tanoubi "Toward a deep convolutional LSTM for eye gaze spatiotemporal data sequence classification" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 672 - 676

participant looked at a 23" HD monitor (1920x1080 px) on which the simulation was broadcasted. A Tobii TX300 eye tracker was attached to the monitor to record their eye-gaze movements. The simulation is based on the Cannot Intubate/Cannot Oxygenate (CICO) algorithm from the Difficult Airway Society to manage unanticipated difficult intubation in adults [9]. The simulation was scripted to integrate various unanticipated and realistic complications. It was recorded using high-fidelity settings and the video had a total duration of 13 minutes.

As a task, the participants were asked to verbalize their clinical reasoning using a think-aloud protocol (recorded with the eye tracker built-in microphone) while watching the simulation video. Specifically, they had to explain what they see in the different areas of interest (Figure 1) to perform their reasoning. In addition, the participants must explain what they would have done as clinician in charge in some key medical and situational awareness events (Table 1) identified throughout the simulation.

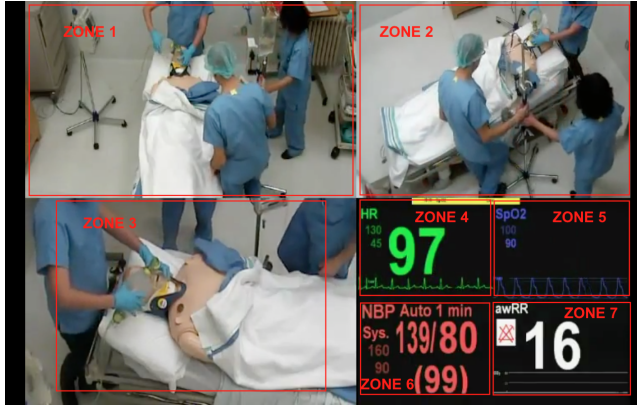

Figure 1: Areas of interest in the simulation

The display screen was divided in seven zones; each representing an area of interest (AOI).

3.2 Dataset

The eye tracker has an accuracy of 0.4deg and was set to a sampling rate of 60Hz. This means that a data point is collect each 17 ms. Each “data point” in the dataset is identified with a $\{x, y, t\}$ tuple by the eye tracker. Overall, our eye-tracking dataset contains about 645k data points; i.e., 14 time series of around 46k points each. Each time series $T = \{p^{(1)} \dots p^{(n)}\}$ is a sequence of 2D vectors, where each vector $p^{(i)} = [x_i, y_i]$ represents the eye-gaze position at a given timestamp t_i .

4. PRELIMINARY ANALYSIS

4.1 Eye movements fixation analysis

First, we conducted preliminary analysis, aimed at providing exploratory insights. For that, we compare novices vs. experts using descriptive statistics on the fixation. For example, the result for the total fixation count and the total fixation duration within each AOI are shown in Figure 2.

These preliminary analysis results showed that both experts and novices have their highest total fixation duration on

(a) Fixation count mean (b) Fixation duration mean

Figure 2: Event count (2a) and mean fixation duration (2b). Error bars denote 95% confidence intervals.

the Technical view (AOI 3) and the General view (AOI 1). This result is further confirmed by the fixation count. Second, novices spent a significantly shorter amount of time at the Saturation view (AOI 5) than the experts ($M = 59$ vs $M = 107$ s, $p = .002$). Inversely, novices spent a significantly higher amount of time at the Technical view (AOI 3) than experts ($M = 382$ vs $M = 266$ s, $p = .042$). All other comparisons were not found to be statistically significant.

4.2 Eye movements behavior around the key events

The video recordings were annotated at different timestamps in terms of clinical keys events. The Table 1 provides an overview of such key event annotations.

Focus Area	AOIs	Time	Description
Healthcare provider	1,3	02:41	Call for help
	1,2,3	03:35	Mask ventilation
	3	06:41	Installation of oropharyngeal cannula
	3	07:35	Use of video-laryngoscope
	1,3	08:33	Use of supra-glottic device
	1,3	09:39	Blue Code initiation
Patient	3	10:32	Initiation of surgical airway
	2	01:10	Impaired verbal response
	3	01:25	Eye closure
Vital signs monitor	1	02:09	Hypoventilation
	5,7	01:37	Desaturation
	4,6	08:33	Bradycardia
	5	10:22	Loss of the saturation signal

Table 1: Key events through the simulation video, together with their relation to the eye tracker AOIs.

With this video annotations, we rendered the heatmaps from raw eye-gaze coordinates corresponding to each key event. We considered eye movement data corresponding to 2 seconds of duration, 1 second before and 1 second after each key event timestamp, given that both eye fixations and reaction times occur typically around 500 ms [8, 15, 19]. Therefore, it allows to capture the eye gaze behaviour before and after each key event.

With this fine-grained video annotations and the observation of the incremental heatmaps around each key events, we observed more salient differences between novices and experts. For instance at 06:41 (Installation of oropharyngeal cannula) we observed a divergent eye movements behavior: both novices and experts focused on AOIs 3 and 5, but novices also focused in AOI 1 (Figure 3). These observations

suggest that both novices and experts have subtle different eye-gaze movement patterns most of the time, while sometimes they are similar. What is most important, these eye-gaze patterns vary over time, suggesting that both novices and experts tend to focus on different AOIs over time.

Figure 3: Heatmap of the eye-gaze coordinates taking into account 1 second before and after the key events at 06:41

5. EXPERTISE CLASSIFICATION BASED ON EYE GAZE SEQUENCE COORDINATES

Taken together, the preliminary and the behavioral analysis suggest that we could build a classification model considering the eye-gaze movements coordinates over time. Based on the outcome and observations from the preliminary analysis, we wondered if we could automatically learn these eye-gaze behaviors and discriminate clinicians' expertise accordingly; i.e., given a particular sequence of eye movements with their coordinates, can we predict if it is a novice or an expert eye movements behavior? That research objective is a two-class (binary) classification problem on spatiotemporal eye gaze data.

5.1 The challenges of sequential data classification

As discussed by Xing et al. [26], there are three major challenges in sequence classification. First, the vast majority of classifiers can only take input data as a vector of features. However, there are no *explicit* features in sequence data. Second, even with various features selection methods to transform a sequence into a set of features, the feature selection is far from trivial. The dimensionality of the feature space for the sequence data can be very high and the computation can be costly. Third, besides accurate classification results, in some applications, we may also want to get an "interpretable" classifier. As previously stated, building an interpretable sequence classifier is difficult since there are no explicit *a priori* features.

There are many approaches that have been proposed to address the problem of sequence classification. We will briefly discuss the two main categories: vector-based and model-based classification. In vector-based classification, a data sequence is transformed into a vector of features through feature selections. Then, we need a distance function to measure the similarity between a pair of sequences. The choice of distance measures is critical to the performance of these classifiers. For simple time series classification, Euclidean distance is a widely adopted option [26]. Since Euclidean distance is sensitive to distortions in time dimension, dynamic time warping (DTW) is proposed to overcome this problem and does not require two time series to

be of the same length [13]. Dynamic time warping is usually computed by dynamic programming and has the quadratic time complexity. Therefore, it is computationally costly on a large data set. Using that vector representation of the data, sequences can be classified by a conventional classification method, such as support vector machines [24], decision trees [4], etc.

In model-based classification, given a class of sequences, an underlying model learns the probability distribution of each sequence. The simplest approach is the Naive Bayes sequence classifier [7]. It assumes that, given a class, the features in the sequences are independent of each other. However, this assumption is often violated in practice. A hidden Markov model (HMM) can learn the dependence among elements in sequences [1, 22], assuming that the system being modelled is a Markov process with unobserved states, where the state is described by a single discrete random variable. In contrast, neural networks do not have these assumptions. Moreover, HMMs can only deal with a limited number of step dependencies, while LSTMs can deal with long-term dependencies.

5.2 Machine Learning Models

Since the objective is to predict the expertise given a particular eye movements sequence, the full-length eye-gaze sequence are sliced in smaller parts. Each instance is a fixed-size time series consisting of the raw eye-gaze coordinates; i.e., (x, y) points (a 2D vector). For our experiment, we used sequence slices of length $s = 1000$, which represent eye-gaze sequences (time series) of about 17 seconds each. Finally, because of the small number of participants, we choose the LOOCV (Leave-one-out Cross Validation) as a resampling technique.

Two machine learning architectures were developed to perform the eye gaze spatiotemporal data classification: a WKM-kNN architecture and a DeepConv-LSTM architecture

5.2.1 WKM-kNN architecture

The WKM-kNN architecture is a composition of warped K-means (WKM) with k-nearest neighbor (k-NN). WKM is a fast algorithm for clustering data sequences based on distances, and has outperformed comparable approaches in the task of sequence classification [17]. In addition to providing a compact representation of data sequences, WKM makes them robust to noise or distortions in such data. The input to this model is a time series (a sequence of 2D vectors), and the output is either novice or expert, according to the k-NN classifier.

The WKM algorithm capitalizes in the sequentiality of the data and starts with a suitable initial partition [16], by using piecewise linear interpolation, which results in a non-linearly distributed initial partition of the data. Then, WKM iterates over the data points using a K-means-like optimization procedure. Finally, the k-NN classifier is a non-parametric instance-based learning method, which is among the simplest of all machine learning algorithms. In this work we use $k = 1$ for classification.

To sum up, the WKM-kNN architecture proceeds as follows: first WKM compresses a time series of length n into c disjoint homogeneous segments (or “elementary units”) with $1 < c \ll n$, then the centroid of each segment is used as input to a 1-NN classifier. As in any other clustering algorithm, the number of sequence chunks c should be provided as input. Therefore, because the optimum c for classification is unknown in advance, we tested different values of c , increasingly from 1 (each time series is reduced to a single 2D vector) to 500 (half of the original sequence length).

5.2.2 DeepConv-LSTM architecture

The DeepConv-LSTM architecture is a neural network consisting of a convolutional block followed by a recurrent block (Figure 4).

The recurrent block is a deep long short-term memory (LSTM) network. LSTMs are a type of recurrent neural networks (RNNs) capable of learning long-term dependencies in time series by selectively remembering patterns for long duration and were developed to deal with the *exploding* and *vanishing gradient* problems of traditional RNNs [2, 20]. LSTMs have outperformed many other approaches in a variety of tasks, such as handwriting [11] and speech recognition [12], therefore we adopted this model to analyze eye-gaze sequences. In addition, inspired by recent work that has applied convolutional neural networks (CNNs) to sequence modeling with great success [3], we add a one-dimensional convolutional layer (temporal convolution) to the network input followed by a max pooling layer, which then feed the consolidated features to the LSTM. In other words, a CNN layer learns spatial features which are then learned as sequences by an LSTM layer. This way, we combine the spatial structure learning properties of CNNs with the sequence learning of LSTMs. On the other hand, the max pooling layer is a sample-based discretization process, with 3 goals in mind: (1) reduce the input dimensionality, by filtering the initial data representation; (2) avoid over-fitting, by providing an abstracted form of the data representation; and (3) lower the computational cost, by reducing the number of parameters to learn.

Figure 4: Deep learning network topology. Notes: The drawing is simplified to avoid visual clutter. Each layer dimensionality (n) is denoted below their title.

Overall, the chosen network has 41311 trainable parameters with the topology shown in Figure 4. The network input is the sequence slices (a sequence of 2D vectors), whereas the network output is either novice or expert. Both the CNN and max pooling layers have a kernel size of 2. The LSTM layer is fully connected with 100 neurons. The dropout layers have a probability of 0.2, since it is the recommended

value for most machine learning scenarios; see e.g. [21, 23]. These layers have the effect of reducing overfitting and improving model performance.

We trained the neural network with 60 epochs and a batch size of 256 (mini-batch training) on an i5 CPU @ 3.30 GHz with 16 GB of RAM. After each epoch, the model is evaluated against the testing partition, to get an idea of how well the model is performing during training, after which the data is shuffled for the next epoch. The model was fit using the efficient ADAM optimization algorithm [14] with binary crossentropy as loss function.

5.3 Results

The Table 2 summarizes the results, in terms of classification accuracy. Together with the confidence intervals, we report the Area Under the ROC Curve (AUC), which is a one of the standardized measure of a classifier’s performance. Since the WKM-kNN architecture was tested at different segmentation values c , we report the best classification accuracy result, which was achieved with $c = 4$ segments.

Model	Accuracy (%)	95% Conf. Int.	AUC
WKM-kNN	72.6	[71.1, 74.2]	0.74
DeepConv-LSTM	84.2	[84.9, 86.4]	0.86

Table 2: Summary of the classification results. Confidence intervals are calculated according to the Wilson method for binomial distributions [25].

6. CONCLUSION AND FUTURE WORKS

This research objective is to collect factual eye gaze data from clinicians during a clinical reasoning task. Given a particular sequence of eye movements, with their coordinates; can we predict if it is a novice or an expert clinician eye movements behavior? To answer that question, we built two machine learning models for the binary classification. The deep learning architecture provides an overall better results achieving a very competitive level of accuracy (84.2%) on eye-gaze spatiotemporal data. These results are particularly striking given the fact that we used the *raw* gaze coordinates coming from the eye tracker. The key for the success of a deep neural network classifier is the ability to automatically learn hidden features or intermediates representations in the input data.

The future work is to use the eye-gaze spatiotemporal data classifier outcome and the recorded expert clinical reasoning during the key events as one of the key milestone for the ITS domain model. Also, we have not studied the impact that eye-gaze sequence length may have on model accuracy, though in general shorter sequences should be harder to classify. Some studies argue that humans make informed decisions in a matter of milliseconds [5] although we suspect this is strongly correlated to the application at hand. Therefore, analyzing this possible impact of sequence length on accuracy is another interesting avenue for future work, which in turn opens many research questions. For example: What is the minimum sequence length that maximizes classification accuracy? Is there any upper bound from which we can devise useful eye-gaze information? Does more segment context overlap lead to better model generalization?

ABSTRACT

Knowledge tracing (KT) models, e.g., the deep knowledge tracing (DKT) model, track an individual learner's acquisition of skills over time by examining the learner's performance on questions related to those skills. A practical limitation in most existing KT models is that all questions nested under a particular skill are treated as equivalent observations of a learner's ability, which is an inaccurate assumption in real-world educational scenarios. To overcome this limitation we introduce *qDKT*, a variant of DKT that models every learner's success probability on individual questions over time. *qDKT* incorporates graph Laplacian regularization to smooth predictions under each skill, which is particularly useful when the number of questions in the dataset is big. *qDKT* also uses an initialization scheme inspired by the fastText algorithm, which has found great success in a variety of language modeling tasks. Our experiments on several real-world datasets show that *qDKT* achieves state-of-art performance predicting learner outcomes. Thus, *qDKT* can serve as a simple, yet tough-to-beat, baseline for new question-centric KT models.

1. INTRODUCTION

Knowledge tracing (KT) models are useful tools which provide educators with actionable insights into learners' progress [21, 16]. Given a learner's performance history, these methods predict their proficiency across a predetermined set of skills (i.e., knowledge components or concepts). One of the most popular methods for tracking this cognitive development is the Bayesian Knowledge Tracing (BKT) framework [3, 15, 24] which applies hidden Markov models [1] to learn each learner's *guess*, *slip*, and *learn* probabilities for each skill. Another approach to modeling the dynamics of skill acquisition is SPARFA-Trace [11] which uses Kalman filtering [9] to model learner skill acquisition. An advantage of SPARFA-Trace is that, unlike BKT models, it can relate individual questions to multiple skills. Recently, deep learning techniques have been applied to the KT problem to create Deep Knowledge Tracking (DKT) [18] which mod-

els the sequence prediction task using a Long Short-Term Memory (LSTM) network [8].

All of the aforementioned KT models track an individual learner's knowledge at the *skill* level. Under the KT framework, the time series data modeled consists of learner skill interaction sequences, given by $X_i = \{(s_t^i, a_t^i)\}_{t=1}^T$ where s_t^i is the skill index attempted by the i^{th} learner at discrete time step t , while $a_t^i \in \{0, 1\}$ is the assessment of the learner's response, with 0 indicating an incorrect response and 1 indicating a correct response.

The key assumption underpinning all of the above models is that all questions nested under a particular skill are equivalent. This assumption, however, is generally unrealistic in real-world educational datasets. First, a mapping of questions to skills is not always available and obtaining such a mapping requires the intervention of subject matter experts, which is both costly and time-consuming. Second, questions in real-world educational datasets are never homogeneous, but rather exhibit significant variations in difficulty and discrimination [5]. In other words, different questions convey differing levels of information about a particular learner's mastery of the underlying skill, and methods for modeling learner's acquisition of skills over time should take such information into account.

However, simply substituting questions for skills in a traditional KT model is insufficient to accomplish the goal of tracking an individual learner's knowledge at the question level. To illustrate this, we selected two commonly used educational datasets, ASSISTments2009 and ASSISTments2017.¹ We first ran the standard DKT model using the skill-level information provided with each dataset. We then re-ran the DKT model but used the question identifiers themselves, rather than the skills, for modeling performance. Concretely, the time series data modeled consisted of learners' question interaction sequences, given by $X_i = \{(q_t^i, a_t^i)\}_{t=1}^T$, where q_t^i denotes the question answered by learner i at time t . The AUC for both of these model variants are shown in Table 1. We note that for the ASSISTments 2017 dataset that this question-centric approach provides a moderate improvement in AUC but for the ASSISTments 2009 dataset the question-centric approach significantly hurt AUC.

To understand why this behavior occurs, we note that the

Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 677 - 681

Dataset	Number of questions	Avg. Obs. per question	DKT (skill)	DKT (question)
ASSISTments 2017	1,183	145.76	0.72	0.74
ASSISTments 2009	16,891	19.27	0.74	0.68

Table 1: AUC scores for DKT vs. its variant with questions as indices. Using questions indices leads to overfitting when the number of observations per question is small.

average number of observations per question for the ASSISTments 2009 dataset is significantly smaller than that for the ASSISTments 2017 dataset. This results in the question-centric modeling overfitting to the data, which adversely affects predictive accuracy. In contrast, the ASSISTments 2017 dataset has a larger number of observations per question, which helps the question-centric DKT model to avoid overfitting.

It is apparent that question-level modeling has the potential to significantly improve predictive accuracy in KT models as compared to skill-level modeling. However, simply substituting questions for skills in a KT model is insufficient to realize the gain. Addressing this challenge is the focus of our work.

Our main contributions are summarized as follows:

1. We propose a novel algorithm for question-level knowledge tracing, which we dub *qDKT*, that achieves state-of-the-art performance compared to traditional KT methods on a number of real-world datasets.
2. Our method utilizes a novel graph Laplacian regularizer for incorporating question similarity information into *qDKT*. Question similarity can be calculated using the skill information or using textual similarity measures if the dataset contains the actual text for each question. Unlike other KT methods, our method does not assume that each question must be associated with exactly one skill.
3. We propose a novel initialization scheme for question-level KT models using fastText [2], an algorithm for natural language processing (NLP). This initialization scheme learns embeddings that summarize pointwise mutual information statistics [12], which is beneficial for bootstrapping sequence prediction models.

Incorporating question-information to improve skill-centric KT models have been tried in the past, for example, the model proposed by [22] concatenates the question embedding to the skill embedding, which is then used as the input to the model. As training progresses, the model learns both the question embedding, and the skill embedding. However, the focus of our proposed initialization scheme is to bootstrap question-centric KT models without using any skill information. As stated earlier, this is advantageous because firstly, tagging questions with skills can be expensive, and secondly, the design of current skill-centric KT models does not transfer well to question-centric KT models (as shown in Table 1).

Initialized with the fastText-inspired scheme, *qDKT* performs at par with the state-of-art skill-level DKT model on ASSISTments 2009 dataset, and improves it by 5% and 6% on the ASSISTments 2017 dataset and Statics 2011 dataset respectively. Coupling the fastText-inspired scheme with the Laplacian regularizer, *qDKT* gives gains of 2% in AUC score as compared to the skill-centric DKT model for ASSISTments 2009, while also capturing question-specific characteristics.

2. PROBLEM STATEMENT AND DKT OVERVIEW

Each learner’s performance record contains the questions attempted, time at which each question was attempted, and the assessment of each response (either correct or incorrect). Also, assume that the skill associated with every question is known. Given performance records for several learners, one wishes to train a knowledge tracing model with the objective of predicting the success probabilities across the questions (or the skills) at time T for a new learner whose performance history has been recorded until time $T - 1$.

2.1 DKT Model

DKT uses an LSTM to predict a learner’s future performance using their previous assessment history. As discussed earlier, the input to the model is a time series which consists of learners’ skill interaction sequences, given by $X_i = \{(s_t^i, a_t^i)\}_{t=1}^T$. Here we restrict our discussion to a single learner and will omit the superscript i throughout. The forward equations of the DKT model are given by

$$\mathbf{x}_t = W_{xv} \mathbf{v}_t, \quad (1)$$

$$\mathbf{h}_t = \text{LSTM}(\mathbf{x}_t), \quad (2)$$

$$\mathbf{y}_t = \sigma(W_{yh} \mathbf{h}_t + \mathbf{b}_y), \quad (3)$$

where σ is the sigmoid function. In words, the input at time step t is the skill interaction tuple (s_t, a_t) which is encoded by an arbitrary high-dimensional one-hot vector, $\mathbf{v}_t \in \{0, 1\}^{2M}$, where M is the number of skills. Using an embedding matrix, $W_{xv} \in R^{K \times 2M}$, \mathbf{v}_t is mapped to a low-dimensional vector, $\mathbf{x}_t \in R^K$, $K \ll M$ (1), which serves as the input to the LSTM cell. \mathbf{x}_t is passed through each of the input, forget, and output gates and, in the end, the LSTM returns \mathbf{h}_t – the estimate of the learner’s current knowledge state. The final output of the model is $\mathbf{y}_t \in R^M$ which predicts the learner’s success probabilities for all the M skills for the next time step $t + 1$.

2.1.1 Loss in the DKT Model

The output \mathbf{y}_t of the DKT model predicts the learner’s proficiency over the skills for the next time step $t + 1$. During training, the assessment (a_{t+1}) of the learner’s response to the question indexed by q_{t+1} is known beforehand. The success probability for the skill associated with q_{t+1} is given by $y_t[s_{t+1}]$. Since DKT assumes that mastery in the skill is equivalent to mastery in any of the questions under it (i.e., all questions under a skill are equivalent), a trained DKT model should predict the success probability at the skill to be the same as the assessment. This rationale motivates the basis for calculating the loss, ℓ_t , at time t , given by

$$\ell_t = l(y_t[s_{t+1}], a_{t+1}), \quad (4)$$

where ℓ is the binary cross-entropy loss.

2.2 Proposed Model: qDKT

We now introduce our proposed method for KT modeling at the question-level, which we dub qDKT. Our method considers a modified problem statement where we estimate a learner's success probability for each question rather than for each skill. Let a learner's question interaction sequence $X = \{(q_t, a_t)\}_{t=1}^{T-1}$ until time step $T - 1$ be given, where q_t denotes the question answered at time t and $a_t \in \{0, 1\}$ is the assessment of the response to question q_t . Our goal is to output $\mathbf{y}_t \in R^N$ which predicts the learner's success probabilities for all the N questions at the next time step $t + 1$. qDKT utilizes the same architecture as DKT as specified in (1) - (3), but with $\mathbf{v}_t \in \{0, 1\}^{2N}$, $W_{xv} \in R^{K \times 2N}$, and $\mathbf{y} \in R^N$. The updated loss ℓ_t from (4) at time t is then given by

$$\ell_t = l(y_t[q_{t+1}], a_{t+1}). \quad (5)$$

We will refer to this model as the *base qDKT model*, where the prefix q denotes question-level modeling.

3. REGULARIZATION FOR qDKT

As seen in Table 1, the base qDKT model performs poorly for datasets with both a large number of questions and a small number of observations per question. To overcome this, we propose a regularization method for qDKT to combat overfitting. It is reasonable to assume that success probabilities of multiple questions associated with the same skill should not be significantly different for a given learner. Based on this premise, we regularize the variance in success probabilities for questions that fall under the same skill

$$R(\mathbf{y}) = \sum_{i \in Q} \sum_{j \in Q} \mathbf{1}(i, j) \cdot (y_i - y_j)^2, \quad (6)$$

where vector $\mathbf{y} \in R^N$ contains success probabilities of all questions Q in the dataset, $i, j \in Q$ and $\mathbf{1}(i, j)$ is 1 if i, j fall under the same skill, otherwise it is 0.

We add this penalty to the loss and use λ to control the weight of the penalty. Thus, the updated loss function from (4) with the regularization penalty is

$$\ell = l + \lambda \cdot R(\mathbf{y}). \quad (7)$$

3.1 Interpretation of the regularizer

Graph theory provides a clean interpretation for the regularization penalty which is also helpful for speeding up its computation. We construct a graph G with number of nodes equal to the number of questions in the dataset. Two nodes are connected with an edge of weight 1 if the questions are associated with the same skill and with an edge weight of 0 otherwise.

The degree matrix D of a graph G is a diagonal matrix with

$$d_{ii} = \sum_{j \in C_i} w_{ij},$$

where w_{ij} is the similarity between node i and node j (edge weight), C is the set containing all the indices directly connected with i (immediate siblings). The adjacency matrix A

of a graph G stores the edge weights w_{ij} . Given the degree matrix D and the adjacency matrix A of a graph G , the Laplacian matrix L is defined as

$$L = D - A.$$

Then for any vector \mathbf{v} [7],

$$\mathbf{v}^T L \mathbf{v} = \sum_{i,j} w_{ij} \cdot (v_i - v_j)^2. \quad (8)$$

We can then use (8) to simplify the regularization penalty of (6)

$$R(\mathbf{y}) = \sum_{i \in Q} \sum_{j \in Q} \mathbf{1}(i, j) \cdot (y_i - y_j)^2 = \mathbf{y}^T L \mathbf{y}. \quad (9)$$

The simplification of the double summation term to a condensed vector-matrix multiplication term is useful to speed up its calculation, especially while training the qDKT model on GPUs.

Further, our approach to model similarity works even when questions are associated with multiple skills. This provides additional flexibility over previous KT models that restrict each question to be associated to exactly one skill. Such flexibility is important for real-world applications where questions commonly evaluate learners on multiple skills simultaneously. Moreover, this formulation can be helpful to incorporate even other measures of similarity like tf-idf similarity [13] using question text.

4. INITIALIZATION OF qDKT

DKT maps each skill interaction tuple to $\mathbf{x} \in R^d$ via the matrix W_{xv} (see (1)). In DKT, the entries of W_{xv} are initialized with draws from a standard normal distribution. While this approach is straightforward, random embeddings tend to perform extremely poorly in high dimensions where the optimization problem will have an extremely large number of saddle points [4]. To overcome this limitation, we propose a more effective method for initializing W_{xv} inspired by the fastText architecture.

4.1 Language Modeling and fastText

In NLP, language models are used to predict the most likely words that can follow a given sequence of words. Such models are often initialized with word embeddings from algorithms like word2vec [14], fastText and GloVe [17]. At a high level, these algorithms embed words into a high dimensional space such that words that have close semantic relationships will be embedded near one another, while words with low semantic similarity will be embedded further apart [6].

A novelty of fastText is that it considers individual characters in a word when computing the final embeddings. By doing this, fastText recognizes that the words "love", "loved", "lovely", and "lovable" are all related and embed them accordingly.

4.2 Embedding Educational Response Data

In our application, we wish to have a notion of question similarity that can serve to guide our initialization scheme, similar to the notion of similar word contexts in fastText.

Dataset	Learners	Questions	Skills	Records
ASSISTments 2009	4,151	16,891	111	325,637
ASSISTments 2017	1,709	1,183	86	249,105
Statics2011	333	1,223	85	189,297
Tutor	895	5981	1,592	437,524

Table 2: Dataset summary statistics.

To do this, we assemble an approximate “text corpus” from our response data, as follows.

Let set Q contain all the question ids and set U contain all characters. We define a one-to-one mapping $f : Q \rightarrow U$ which maps a question id to a unique character. To convert learners’ question interaction sequences, $X = \{(q_t, a_t)\}_{t=1}^T$ into a text corpus, we apply a signal transformation Y on X such that $y_t = f(q_t) + a_t$ where ‘+’ denotes the string concatenation operator. Thus, each question interaction is encoded as a two character string consisting of the question id and the graded response. This interaction encoding constitutes the “words” of our corpus. The “sentences” of our corpus constitute of the string of such encoded interactions by an individual learner. We finally apply fastText to this newly generated “corpus”. For a given question interaction say $(q, 0)$, fastText will train the embeddings of the following n -grams $\{f(q), '0', f(q) + '0'\}$. Thus, we link the embeddings of $(q, 0)$ and $(q, 1)$ through the embedding of $f(q)$. The resulting output embedding of fastText is used as our initialization of W_{xv} .

5. EXPERIMENTS

5.1 Datasets

We consider four datasets for our experiments: ASSISTments 2009, ASSISTments 2017, Statics 2011, and a dataset from OpenStax Tutor, an online learning platform. The Statics 2011 dataset is from an engineering statics course. Standard pre-processing steps common in the literature are used to clean the data. For ASSISTments2009 dataset, we follow the pre-processing steps recommended by [23]. Duplicated records and scaffolding problems are removed. Also, since the dataset contains a few questions that are associated with multiple skills, those multiple skills were combined into a new joint skill for skill-level DKT models, along the lines of [23]. However, for qDKT, our Laplacian regularization approach provides needed flexibility when questions fall under multiple skills, doing away with the need of combining multiple skill into one joint skill. For the ASSISTments2017 dataset, all scaffolding problems are filtered out. Relevant statistics for each dataset are given in Table 2.

5.2 Experimental Setup and Metrics

Each experiment consists of comparing our proposed qDKT algorithm against the original DKT algorithm for a given dataset. To further quantify the impact of each proposed improvement to the qDKT model we will measure qDKT performance over four different variants: 1) The base qDKT without any regularization and with randomized initialization, 2) qDKT with regularization and randomized initialization, 3) qDKT without regularization but with our proposed initialization scheme and 4) qDKT with both regularization and with our proposed initialization scheme. For all the experiments and datasets, we perform 5-fold cross validation; 70% data is used for training and the rest for

testing. We report the average receiver operating characteristics curve (AUC) score to compare each method. All the models are trained using the Adam optimizer [10] with dropout [20] to reduce overfitting.

5.3 Results and Discussion

Our results are displayed in Table 3. We see that the base qDKT model without regularization and with randomized initialization outperforms the original DKT model on three of the four datasets used. For the ASSISTments 2009 dataset, base qDKT loses by a large margin. This is due to ASSISTments 2009 dataset having a large number of questions coupled with a low number of observations per question (see Table 1). We note that the individual addition of either the regularizer or the fastText initialization scheme greatly improves the performance of qDKT for each dataset. We finally note that the combination of both the regularizer and fastText initialization scheme enables qDKT to achieve better performance than DKT for all datasets considered.

For additional details, please refer to the extended version of this paper [19].

6. CONCLUSIONS

We have proposed qDKT, a novel model for knowledge tracing for educational data. Our method improves on prior art by predicting student performance at the question-level, rather than at the skill level. We have further proposed novel regularization and initialization schemes that greatly improve the performance of our method across several real-world datasets when compared with the traditional knowledge tracing methods. We propose that qDKT can provide a simple, yet tough-to-beat baseline, for new question-centric KT models to come.

ABSTRACT

Massive Open Online Course (MOOC) has been inefficient in responding to students' questions, or in-lesson comments as the volume of questions is truly massive. This paper proposes a framework that utilizes students' behavioral data on the web in addition to text data in answering student questions. With this framework, we built a recommender system that generates a set of ranked video snippets in response to a student's question by implementing a deep neural network for question and confusion classifiers and a content-based recommender for providing answers to the student's question. Preliminary results show that our question and confusion classifiers outperform the baseline models. Our combined recommender model shows the best performance in recommending the answer. As an ongoing endeavor, we are in the process of developing an intelligent agent that leverages the question and confusion classifiers in improving student's achievement.

Keywords

MOOC, Recommender Systems, Question Answering

1. INTRODUCTION

Given the millions of users who are using a Massive Open Online Course (MOOC) platform for their studying, instructors cannot answer all the questions from their students. Consequently, discussion forums are leveraged to facilitate peer-to-peer learning. However, this approach has the potential of misleading each other with inaccurate information as well as the lack of responsibility and participation, thereby contributing to duplicate questions and early dropouts [6]. A few studies developed a question answering model to mitigate the aforementioned problems. YouEDU [1] presented an approach that automatically detects confusion in MOOC forum posts and recommends video clips as answers in a specific course forum. Xiao-Shih [3] is the intelligent educational question answering bot made of Natural Language

^{*}The corresponding author.

Patara Trirat, Sakonporn Noree and Mun Yong Yi "IntelliMOOC: Intelligent Online Learning Framework for MOOC Platforms" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 682 - 685

Processing (NLP) processes and a Random Forest model to answer learners' questions. While these approaches provide some answers to the problem, they primarily targeted at students who actively participate in the course discussion forum. Still, learners who use forums are a very tiny part of course learners. Further, behavioral traces can help identify periods of confusion and the reasons behind [6].

In this paper, to provide a better learning experience on the MOOC platform, we extend prior research by incorporating the idea of detecting student's confusion as in [2, 5, 6, 7] but using web data rather than text data in order to have more responsiveness and interactivity within a single webpage. The methodology and preliminary results are presented in Section 2 and Section 3, respectively.

2. METHODOLOGY

In this section, we present the data set used in this paper, classifiers, recommender models, and ongoing work. We decided to adopt the *Khan Academy* data set, as described in the following subsection. The post data from the discussion forums commonly used by prior work are not employed in our study because our ultimate goal is to develop a single page learning environment for MOOC (Section 2.5) that resembles the Khan Academy environment for a seamless learning experience. Also, given that Khan Academy provides a diverse set of courses in which our approach is validated, using the Khan Academy data set was preferred for generalizability.

2.1 Khan Academy Dataset

As illustrated in Figure 1, we collected the 9,772 videos, 469,474 questions, and 1,048,575 video transcripts through the Khan Academy API¹. Because the length of the given transcripts was too short, only a single sentence for each transcript, we merged them into the list of captions (one-minute long each) by calculating the number of snippets using equation (1).

$$\text{number of snippets} = \left\lceil \frac{t_{\text{end}} - t_{\text{start}}}{60} \right\rceil \quad (1)$$

After that, we used the number of snippets to compute the number of captions by equation (2), resulting in 72,313 captions.

$$\text{number of captions} = \left\lceil \frac{\text{number of transcripts}}{\text{number of snippets}} \right\rceil \quad (2)$$

¹<https://github.com/Khan/khan-api>

Table 1: Description of Features used for training the Confusion Classifier.

Name	Description	Example
replay	Is the video replayed?	0
playback speed	Speed of the video.	0.5
caption	Is caption of the video opened?	1
return	Does a student watch at a previous specific time point?	0
return counts	How many time a student jump to a previous specific time point?	3
forward	Does a student watch at a next specific time point?	1
forward counts	How many time a student jump to a next specific time point?	2
watch counts	How many time a student watch the entire video?	2
pause	Is the video currently paused?	0
pause counts	How many time a student pause the video?	5
volume up	Is the volume increased?	1
volume down	Is the volume decreased?	0
resolution	What is the quality of the video selected?	720

In the question dataset, as many questions were invalid questions (i.e., with the attribute *flags* of inappropriate, comments, misplace, or spam), we utilized a few attributes provided by the Khan Academy API to label each question in building a classifier as follows.

- **flags.** If a user flagged the question, we considered it as a statement. The possible flags are, for instance, *inappropriate*, *changetocomment*, *doesnotbelong*, and *spam*.
- **lowQualityScore.** This attribute shows the quality of the given question. From our observation, we decided to use 0.7 as a threshold, meaning that a sentence with a score of 0.7 or lower is considered a valid question. Further, we noticed that the sentences with the *lowQualityScore* of greater than 10 is also valid. These sentences were all related to a sexual reproduction course and were all valid questions.
- **not_spam.** If value of *not_spam* is true, we considered it as a real question.
- **sum_vote.** The *sum_vote* is incrementally accumulated by the vote of the students (including the one who posts). If the *sum_vote* is greater than 2, we considered it as an actual question.

Finally, we extracted the referenced time from the questions using the regular expression technique when we computed the similarity between the question and captions in the recommendation stage.

2.2 Classifiers

In the classification stage, we set the dependent variable of the data set as a binary class (1 or 0) for both *Question* and *Confusion* classifiers: 1 indicates a real question (by Question Classifier) or student’s confusion (by Confusion Classifier), 0 otherwise.

2.2.1 Question Classifier

We built binary classifiers applying various approaches – both Machine Learning (e.g., Logistic Regression, Random Forest, and SVM) with TF-IDF and Deep Learning (e.g., MLP, CNN, GRU, and LSTM) with the GloVe [4] pre-trained word vector. Regarding training and testing datasets, we had all of the questions go through the NLP processes to extract the tokens of each question. We kept Wh-words and question marks as we found that they had some discriminant power. We used 85% of the dataset as a training set, and the remaining as a testing set.

2.2.2 Confusion Classifier

To build a confusion classifier, we trained bidirectional Gated Recurrent Units (GRU) for classifying the sequences of users’ behavioral log data. As a preliminary evaluation, because the clickstream study data was lacking diverse scenarios, we instead synthesized 100,000 log data (ten sequences each) to simulate the students’ behaviors. The features of the synthesized data are described in Table 1.

2.3 Recommender Models

We built three models, of which the differences were the inputs used to compute the similarity as follows.

- **Baseline.** This model was straightforward. We built it by computing the similarity between the video’s captions and the questions, both of which went through the same NLP steps.
- **Combined.** This model applies the same NLP processes as the previous one, but use more input text. Instead of using only video’s captions, we concatenated the video’s *metadata* to its captions to assign more weights on some specific topics of the video (e.g., Algebra, Renaissance in Italy, and Biology).
- **Noun-based.** This model used the same combination as the previous one but kept only the nouns and noun phrases of the questions and the video’s captions.

In addition to the different input processes of each model, the primary tasks were token vectorization, similarity metric calculation, and time reference extraction. A process after NLP steps was vectorization. We used TF-IDF to build the feature vector of each question and the video’s captions. Subsequently, using the time reference extraction, we concatenated the caption text of the referred time to assign more weights on the specific topic by the specified time in the question. Lastly, we used cosine similarity to calculate the closeness between a question and each of the captions.

2.3.1 Ranking and Recommending Videos

After computing the similarity score between the given question and captions of every video, we sorted the similarity score descendingly in order to select the *top-5 ranked* videos to create a recommendation list. Further, our additional objective was to recommend the videos that can answer the question within a period of one-minute length. Thus, the starting time of the video – that the model ranks and recommends – is the same start time of the caption that matches the question.

2.4 Ongoing Development

We are further working on developing two modules to make the learning environment more interactive and intelligent as follows.

Faster Question Answering. To make the system respond faster and remove potentially duplicated questions more effectively in online settings, we cluster similar questions in meaning that contain the same answer set so that we do not need to compute the similarity between the new question and all of the videos’ captions again. In essence, we

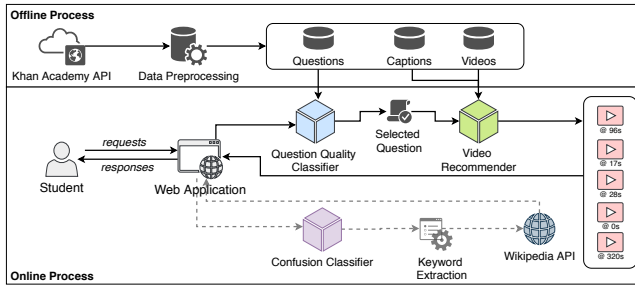

Figure 1: Overview of the proposed framework. The dashed-lines indicate our ongoing work.

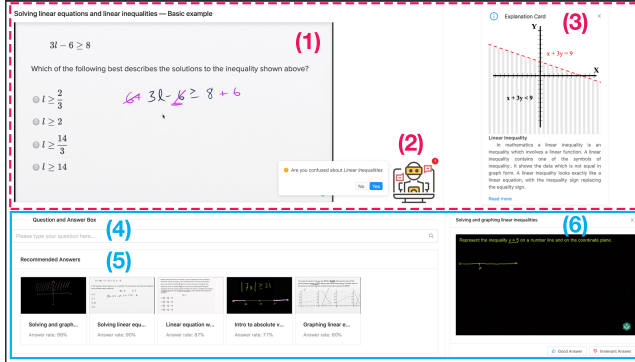

Figure 2: Screenshot of IntelliMOOC prototype.

need to compute only with the question clusters. We also adopt the voting idea to re-compute the weights of the video snippets using the like and dislike interactions as feedback of the student. As a result, students will get the most useful answer at the top while requiring less time.

Intelligent Agent with Confusion Detection. To make it more personalized and interactive, we are in need to develop an intelligent agent, which stays side-by-side to the student, for encouraging the student to ask a question or giving an additional explanation when the student is struggling in a particular topic. For this purpose, we have developed a module that utilizes the feedback from the student’s interaction for re-training the classifier in order to improve the model over time incrementally.

In sum, as shown in Figure 1, we propose a framework based on the techniques above that can work with any MOOC platform by linking the existing discussion forum to the course video pages, so that we can mitigate the dropout and no response problems caused by the confusion that arises during the study [6]. In the next subsection, we describe how we combine those techniques to develop a prototype.

2.5 Prototype of IntelliMOOC

As illustrated in Figure 2, we built a prototype of the IntelliMOOC as the web-based platform consisting of six components in the two modules described above. In the upper segment, it composes of (1) video player, (2) intelligent agent, and (3) explanation card using confusion classifier with keyword extraction and Wikipedia API. In the lower segment, it includes (4) question input box, (5) recommended answer

set, and (6) answered video player using question classifiers with recommendation model. The connection of the underlying processes of each component is depicted in Figure 1. This framework shows how integrating those elements in a single page can provide a better learning experience for the MOOC platform.

3. EXPERIMENTAL EVALUATION

In this section, we show the performance of the classifiers and recommender models. In a standard information retrieval project, the objective is to get the top documents that meet a user’s query. In this work, the query is a question, and the document corresponds to a caption. Our purpose is to retrieve a ranked recommend set of videos that can effectively answer the question.

3.1 Classifiers

We quantified the performance of the classifiers using the two metrics: *Accuracy* and *F1 score*.

Accuracy is the most straightforward standard evaluation metric commonly used for classification models. It measures how the model correctly classified the data.

F1 score is the weighted average score of *Precision* and *Recall* metrics. It is used in this study to examine whether our model still performs well under the class imbalance setting—roughly 3:1 in our case—as it takes both false positives and false negatives into consideration.

Accordingly, we found that the *bidirectional GRU* performed the best in the accuracy and F1 score altogether, achieving **0.84** and **0.78** for the question classifier and **0.997** and **0.99** for the confusion classifier, respectively.

3.2 Recommender Models

We evaluated our recommender models using two metrics: *Parent-Relevancy Score* and *Normalized Discounted Cumulative Gain*. The definition of the two metrics are as follows:

Parent-Relevancy score measures the relevancy between the real topics of the question and the parent topics of the recommended videos. The measurement is divided into two levels. (1) *Root-Level* match is defined as the correct match between the root parent topic of the question and the root parent topic of each video in the recommended set. (2) *1-Level* match is defined as the correct match between at least one parent topic of the question and at least one parent topic of each recommended video regardless of its level.

Normalized Discounted Cumulative Gain (NDCG) computes the sum of the relevance scores (gain) of each recommendation to measure the ranking quality. Nonetheless, the gain is proportionally discounted to how much lower the video is in the ranking. The underlying intuition is that the gain due to a relevant video that appears as an earlier choice should be penalized smaller than it would be if it appeared as a later choice. If $score_i$ is the gain connected with the video at position i , the Discounted Cumulative Gain (DCG) at a position i is defined as:

$$DCG_p = \sum_{i=1}^p \frac{score_i}{\log_2(i+1)} \quad (3)$$

Table 2: Parent-Relevancy scores of each model with the best score obtained by *Combined model*.

	Baseline	Combined	Noun-based
Root-Level	0.667	0.703	0.663
1-Level	0.741	0.760	0.707
Average	0.704	0.732	0.685

Figure 3: Normalized Discounted Cumulative Gain (NDCG) from each rater with the best score at 0.97 and average score at 0.68, both obtained by the *Combined model*.

We used a score relevance scale of 0, 1, 2, and 3, corresponding to the classes listed below and calculated the DCG for the ranked recommendations we received for each question. The Ideal value of DCG (IDCG) is defined as the DCG based on the ideal ranking as assessed by the raters. To get the IDCG, we order the rankings given by the raters in decreasing order of relevance scores and compute the DCG of the sorted ranking. It corresponds to the maximum theoretically possible DCG in any ranking of the recommendations for the given question. We normalize the DCG for our ranking by the IDCG to make the Normalized DCG (NDCG):

$$NDCG_p = \frac{DCG_p}{IDCG_p} \quad (4)$$

If there are n recommended videos, then we report $NDCG(n)$ as $NDCG$, the overall rating for the ranking.

To evaluate each model, we randomly sampled questions from the Khan Academy data set. Regarding *Parent-Relevancy Score*, we randomly chose 50 questions out of 353,067 questions in the data set and performed five-time iterations to get the average score of each model. In the case of $NDCG$, we randomly selected eight questions from the data set and two new questions from the raters. The raters comprised of one undergraduate and four graduates as the courses were mostly high school courses and introductory undergraduate courses. Each recommender would output the result sets to each rater. They independently evaluated the relevance of each recommended video to the given questions. This process yielded a human-generated ranking, which we then compared to the algorithm's rank order. The rating scale given to the raters is shown below, which is similar to [1]:

- 3: **Completely Relevant** the recommended snippet precisely answer the question.
- 2: **Relevant** the recommended snippet is somewhat useful for answering the question.
- 1: **Somewhat Relevant** the title of the recommended snippet is only relevant to the question.
- 0: **Not Relevant** the recommended snippet is not relevant to the question.

As shown in Table 2 and Figure 3, the *Combined Model* is the best model in recommending ranked video clips in each of the evaluation metrics.

4. CONCLUSION

We propose a framework that includes a recommender model, which answers a student question by recommending a set of relevant video snippets. The experiments showed promising results for both of the question and confusion classifier as well as the recommender model. In particular, the *Combined Model*, which utilizes both of the part of speech (noun, verb, and adjective) and video metadata, produced the best results, outperforming the baseline and noun-based models. Our ongoing research is being carried out to enhance the student learning experience by integrating an intelligent agent into the system, which can timely detect a student's confusion using web data.

ABSTRACT

Metacognition is a valuable tool for learning, particularly in online settings, due to its role in self-regulation. Being metacognitive is especially crucial for students who face exceptional difficulties in academic settings because it grants them the ability to identify gaps in their knowledge and seek help during difficult courses. Here we investigate metacognition for one such group of students: college students traditionally underrepresented in STEM (UR-STEM) in the context of two online university-level STEM courses. Using an automatic detection tool for metacognitive language, we first analyzed text from discussion forums of the two courses; one as a prototype and another as a replication study. We then used association rule mining to uncover fine-grained relationships in the online educational context between underrepresented STEM student status, online behavior, and self-regulated learning. In some cases, we inverted association rules to find associations for underrepresented minoritized students. Implications of the results for teaching and learning STEM content in the online space are discussed. Finally, we discuss the issue of using association rule mining to analyze commonly occurring patterns amongst an uncommon smaller subset of the data (specifically, underrepresented groups of students).

Keywords

Metacognition, Association rule mining, Rare itemsets, STEM

1 INTRODUCTION

The troubling underrepresentation of certain groups of people in STEM majors and careers is a multifaceted and complex issue that does not have one single cause and therefore one single solution. Thus, in this paper we utilize a multi-step research design that involves innovative ways to capture what may or may not be contributing to the underrepresentation of certain students in STEM, specifically through online STEM courses at the university level. In the current study we use student demographic data to understand fine-grained relationships in online learning behaviors, analyzed in ways that are not common in this field of research. Specifically, we inverted what association rule mining was originally constructed to do, which we will discuss in this paper.

1.1 Metacognition and the Online Space

Especially in higher education contexts, where learning responsibilities often fall more on the student than the instructor, it is important to understand the behaviors related to students' academic Hannah Valdiviejas and Nigel Bosch "Using Association Rule Mining to Uncover Rarely Occurring Relationships in Two University Online STEM Courses: A Comparative Analysis" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 686 - 690

successes and failures. One behavior that oftentimes separates a successful student from a struggling student is metacognition [11]. Amongst metacognitive research, three main branches of metacognition have been distinguished: metacognitive knowledge, metacognitive monitoring, and metacognitive regulation [7]. For the sake of this research, we focus on metacognitive monitoring, as it is the critical point in order for metacognitive regulation to take place [3].

Metacognitive monitoring, or being conscious of what you do and do not know, is especially critical in online courses, because the burden of guiding and monitoring learning rests more on the student than in traditional learning environments [18]. To be a successful student in an online setting, where being self-regulated is crucial to academic success, the ability to be aware and strategize one's thinking is of the utmost importance. Students who accurately assess their mastery of a concept know how to take effective measures for studying that reflect this judgment of learning. This is called *calibration* and it can be detected through metacognitive monitoring [6]. Traditionally, metacognition in educational contexts has been analyzed according to interventions and surveys; however, this has been shown to be unreliable [15]. More often than not, metacognitive monitoring, a form of self-regulated learning, occurs subconsciously, making it difficult for students to accurately report this [9]. It is for this reason that we use an automatic metacognitive language detection tool [5], in order to avoid invalidities in traditional metacognition measurement.

1.2 Underrepresented Students in STEM

In the United States, an important issue remains unsolved year after year: that is, the vast underrepresentation of African American, Hispanic, Native American, first-generation, and non-male students in STEM majors and careers [2]. As if this were not troublesome enough, with each vertical stage in the academic process, the underrepresentation of these students gets worse [2]. A large underrepresentation of these students, and in turn, a large overrepresentation of people who do not identify with these demographic markers poses a serious bias in the trajectory of the nation, with only a small and homogenous group of people controlling sectors of business and research that are the engines of the nation's economy and innovation [14].

With the concern for students underrepresented (UR) in STEM existing throughout these students' educational trajectory, we argue that much can be learned by examining behaviors related not just to what might impede, but also what might support, these students' success in their STEM college courses to later improve representation in STEM fields. As online education continues to grow [1], its flexibility has made it a very attractive option for underrepresented students in STEM [4]. While online education does offer many options and benefits that traditional face-to-face education does not,

it must not only improve access to college courses among traditionally underserved students, but it must also support the academic success of these students. The purpose of this investigation is to document and understand some of the affordances of the online context for UR-STEM students in online STEM college courses.

1.3 Association Rule Mining

Unlike correlation analysis, which is bivariate, association rule mining can discover relationships among multiple variables at the same time [17]. Specifically, association rule mining aims to find “if-then” rules of the variables, in the form of “antecedent \rightarrow consequence,” where antecedent and consequence are conditions that some variable(s) has certain value(s). While association rule mining is extremely useful for exploratory analyses of large data, researchers have only recently attempted to grapple with a main issue of this tool: its inability to catch important, yet uncommon association rules [15]. This shortcoming of association rule mining poses an obstacle.

A handful of prior association rule mining research endeavors have expressed concern and proposed methods to remedy this issue. For example, [13] proposed confabulation-inspired association rule mining for finding rare itemsets. [12] stressed the importance of high-utility infrequent itemsets in fields like biology, banking, retail, and market basket analysis because of how infrequent itemsets find the hidden rules of association among the data items. In their research, they propose a Utility Pattern Rare Itemset (UPRI) algorithm to handle these scenarios. In terms of educational data mining, [16] explains that researchers will likely only find normal behavior in association rule mining because that is the most frequent behavior. To remedy this issue, [16] developed a new algorithm based on the Apriori approach to mine fuzzy specific rare itemsets from quantitative data, consisting of sets of items that rarely occur in the database together.

The current study aims to bring awareness to using association rule mining to catch rules amongst an already known subset of the participants, within the large dataset, rather than first mining in order to *discover* a subset group of the data that has characteristics in common. In this particular case it is minoritized underrepresented STEM students within a normal STEM online course. We applied association rule mining to explore the associations among variables pertaining to these students. For example, a possible rule in this study might be “non-male \rightarrow no prior online experience.” That is, if the student is a non-male, they are likely to have no prior online experience. Given that association rule mining tends to find frequent itemsets, we propose a modified approach in order to answer our research questions.

We ask the following research questions (RQs):

RQ1. What fine-grained relationships amongst underrepresented STEM students, their demographic information, and their metacognitive language can be uncovered through association rule mining?

RQ2. Although created to find commonly occurring sets of rules, can association rule mining be used to find sets of rules in an uncommon population (underrepresented students in STEM), within a larger set of data?

2 METHOD

In order to answer our research questions, we used demographic information from students in two online STEM courses and discussion forum posts from the same two courses to uncover fine-grained relationships between online learning behavior and student demographic variables.

2.1 Participants and Data Source

2.1.1 Discussion Forum

We analyzed all forum posts (7,040) from 205 students from one (8-week) term of Course A as well as all forum posts (6,086) from 77 students from one (16-week) term of Course B at a large Midwestern public university in the United States. All prompts that corresponded to the forum posts were open-ended with much flexibility for students to answer. Data included all of the students’ discussion forum posts as well as their final course grades, which were provided to us by university data curators. Specifically, there were four levels of grades: A, B, C, and D or lower (we combined D and F grades to avoid identifying students from this small group). In both courses, forum participation was required as part of students’ participation grades. Students were required to regularly post questions they had, or to answer other students’ questions. Online forum activity was 25% of their grade for students in Course A and 5% of their grade for students in Course B.

We used the [5] metacognition tool in order to count metacognitive phrases spontaneously produced by the students in their forum posts. We used this count to relate evidence of self-regulated learning behaviors to students’ background information. This tool also categorizes metacognitive language as being positive or negative; however, for the sake of this study, we only used total count.

2.1.2 Participants

Table 1 describes students’ demographic characteristics. Note that the total number of students across the subsamples is greater than the total of all students because some students belonged to more than one group. We do not report intersectional group level findings of students who fit multiple UR categories, to protect students’ identities and comply with FERPA regulations.

2.2 Data Analysis

Association rule mining has been used in educational contexts to find out relationships between variables, particularly in datasets with many variables [10], like in the current datasets (e.g., ethnicity, prior online experience, ACT score (a standardized test used for college admissions in the United States), grades, metacognitive language count).

Initially we used association rule mining tool as it was intended to be used but only found obvious associations, like those who are STEM majors are likely to have prior subject experience, with none of them dealing with underrepresented students in STEM. This is because their actions were not frequent compared to those in the majority (i.e., STEM majors) and therefore did not get detected as association rules. The current study’s process of association rule mining was inverted, meaning that the minimum support and lift values were set low because the target population was vastly underrepresented in the dataset. This included taking the inverse of many dummy variables where the majority was reflected rather than the minority; for example, we changed the variable “STEM major” to “Non-STEM major” so that we were mining for rules associated with the minority rather than the majority and the unlikely versus the obvious likely. In other words, all of the variables were changed to reflect the minority rather than majority in order to avoid excluding uncommon associations in these courses, especially dealing with minority groups. Therefore, we were actually looking for sets of *less* likely associations, relative to the total amount of associations, rather than likely associations. To identify interesting rules, the FP-Growth algorithm was used with a minimum Support value of 0.10, because the minimum population size

of some underrepresented student category groups that we looked at (non-males, racial/ethnic minoritized students, and first-generation) were just above 15% of the total population. In other words, if the minimum Support value was set higher than 0.15, it would not capture any of the association rules of the target population and if the minimum Support value were set right at 0.15, it would only capture those association rules in which all of the students pertaining to a specific category exhibited a particular rule. We selected a maximum Lift value of .89 since we wanted to find rules that were not associated with each other. High association, or associations that occur more than expected, are indicated by a Lift value > 1 in traditional uses of association rule mining. Therefore, a Lift value < 1 translates to events that happened less than expected. Through trial and error, we discovered that a Lift value set any lower than 0.89 would be too general and would generate too many rules. A Lift Value set higher than 0.89 gets too close to a high association value, excluding too many rules related to the underrepresented population we were interested in. Rules satisfying the criteria are defined as “interesting” in the sense that they were less likely to happen.

3 RESULTS

3.1 Descriptive Statistics

205 students in Course A produced a total 11,417 metacognitive phrases in 7,007 forum posts. The average number of metacognitive words per student was 55.69 (SD = 24.18). The final exam score was out of 170 points, and scores were approximately normally distributed. The minimum score a student received on the final exam was 69.26 and the maximum was 180 (with extra credit). The 77 students in Course B produced a total of 475 metacognitive phrases and 1,939 forum posts. The mean number of metacognitive phrases per student was 6.17 (SD = 5.07). Table 1 shows a percentage breakdown of the variables used in association rule mining in order to conceptualize Support values. *URM* signifies underrepresented racial/ethnic minoritized students in STEM (African American, Hispanic, and/or Native American), *First-gen.* signifies first generation college student (neither parent completed a higher education degree), *No Prior OL* refers to a student having no prior experience with an online course, a higher poster is a student who posts more than the class average (34 for Course A and 13 for Course B), *Low Exam* refers to the student getting a score lower than the class mean, *Course Rep.* refers to students taking the course for a second time (repeating), and *Non-tr. Age* refers to students older than 22.

Table 1. Student breakdown of variables used

Course A	205 Students	Course B	77 Students
Non-males	25%	Non-males	47%
URM	15%	URM	19%
First-Gen	16%	First-Gen	22%
No Prior OL	25%	No Prior OL	29%
High Poster	45%	Course Rep.	19%
Low Exam	47%	Non-Tr. Age	31%

3.2 RQ Answers

Table 2 shows the association rules that were likely to take place, or associations with a Lift value > 1 and Table 3 shows the association rules with a Lift Value < 1 that were less likely than average to occur. The meaning of each variable follows that of Table 1. The new variables include *Low Total MC* which signifies the student

produced less metacognitive language than the average of that class, *High Total MC* phrases refers to students producing more than the average for that class, and prior subject experience refers to students who have had experience with their current course’s subject. The strongest associations have Lift values > 1.00 and the weakest association all have Lift values < 1.00 .

3.3 Likely Association Rules

The two rules from Course A in Table 2 involve the *likely* associations among variables. In particular, the rule “High poster \rightarrow Non-male and isolates a strong association regarding who, of the underrepresented students in STEM, is engaging most in beneficial educational behaviors like posting often. “First generation \rightarrow Low total metacognition” suggests that first-generation students are not engaging metacognition as much as their peers.

The last two rules from Course B in Table 2 involve *likely* associations. The rule “Non-male, Non-traditional age group \rightarrow Low grade” suggests that non-males who are older than 21 are likely to receive lower grades than their peers. The rule “URM \rightarrow More than 4 metacognitive comments, Low grade” indicates if a student identifies as a URM, they are likely to engage in high amounts of metacognitive language but receive a low grade.

Table 2. Likely associations (Lift > 1)

	Antecedent	Consequence	Support	Lift
Course A	High poster	Non-male	0.13	1.16
	First-Gen	Low total MC	0.10	1.15
Course B	Non-male, Non-tr. age	Low grade	0.12	1.50
	URM	High total MC, Low grade	0.07	1.66

3.4 Less Than Average Association Rules

The first four rules from Course A in Table 3 involve the *unlikely* associations among variables. These are not simply the inverse of the most likely rules, because the minimum Support value was not changed, only the Lift. The rules “High poster \rightarrow Low metacognition” and “High poster \rightarrow Low exam” suggest that students who post often rarely exhibit low amounts of metacognition and rarely get low exam grades. The next two rules, “Low total metacognition, Low Exam \rightarrow Prior subject experience” and “Low metacognition \rightarrow Non-male”, indicate that the relationships between low metacognitive language and low exam score are rarely found amongst students with prior subject experience and non-male.

Table 3. Unlikely Associations (Lift $< .89$)

	Antecedent	Consequence	Support	Lift
Course A	High Poster	Low MC	0.09	0.55
	High Poster	Low Exam	0.09	0.70
	Low MC, Low Exam	Prior Subject Experience	0.06	0.73
	Low MC	Non-male	0.09	0.86
Course B	First-Gen, URM	No prior OL	0.06	0.79
	High total MC	Course repeat, Low grade	0.15	0.84
	First-Gen, Non-male	High total MC	0.19	0.87

The next three rules in Table 3 are unlikely associations from Course B. The rule “First generation, URM → no prior online experience” describes that if a student identifies as first-generation and as an URM, they are likely to have prior online experience. The rule “More than 4 metacognitive phrases → Course repeat, Low grade” indicate that it is unlikely for students to have negative educational outcomes if they are engaging in high amounts of metacognitive language. Lastly, the rule “First generation, Non-male → More than 4 metacognitive comments”, suggesting if a student is a first-generation and a non-male, it is highly unlikely that they are engaging in a high amount of metacognitive language production.

4 DISCUSSION

Based on the association rule mining analysis that was performed on data from an online Course A, there is evidence that suggests increased posting in this online course is associated with beneficial educational outcomes, like engaging in metacognitive learning strategies and obtaining a high exam grade. A more obvious rule uncovered through this analysis is that prior subject experience is also associated with beneficial educational outcomes. Some insight that rule mining provided about this course is that non-male students, although underrepresented in STEM, generally did well in this course while first-generation students did not fare as well.

Association rule mining also uncovered important information about students in Course B. A stark difference from Course A is that non-male students did not do as well in this course as in Course A. In Course B, being a non-male older than 22 years old was associated with getting a lower grade in the course. Being a non-male in general as well as being a first-generation college student was associated with uttering the least number of metacognitive phrases of all groups compared (gender, first-generation, and URM).

Underrepresented racial/ethnic minoritized students were the most likely group of students, amongst those compared, to produce metacognitive language; however, being a minoritized student was still associated with getting a lower grade in the course. This is an interesting finding because in Course A, the production of metacognitive language was positively related to course outcome however, in Course B it was not. Through association rule mining it is seen that the more metacognitive phrases a student produced, they less likely they were to display non-beneficial educational behaviors (i.e., repeat the course or receive a low grade).

Perhaps the most interesting finding of this analysis is that underrepresented racial/ethnic minoritized and first-generation college students were very likely to have prior online experience, but only for one course. Initially, before mining for association rules, we thought that a possible factor exacerbating the STEM achievement disparity was the digital divide, or the lack of experience that certain populations have with technology [8]. However, there is evidence that this is not the case. Along with research explaining that online education is an attractive option for underrepresented students [19], we see it is likely that underrepresented students have had prior experience with online education. Knowing this, educational researchers could hone in on this advantageous likelihood of experience with online courses to help lessen the underrepresentation of these students in STEM. The fact that this finding was only present in one course and not the other entertains explanations related to how there might be underlying similarities amongst students related to the types of courses they take, even within the STEM discipline.

4.1 Implications

Right now is a crucial time in higher education because of the apparent transition into more of an online state than ever before. We also know that online education is an attractive option for underrepresented students in STEM for various reasons (e.g., flexible class time). That being said, much work needs to be done in understanding academic outcomes in online education, especially for student underrepresented in STEM, because although it has great positive potential it also has the potential to worsen the lack of certain students in STEM majors and field.

The current study also indicates that association rule mining can, in fact, be used in other ways that it was not intended for, and in this case, to find commonly occurring sets of rules in an uncommon population (URMs), within a larger set of data. This opens the possibility for association rule mining to become a prevalent tool to be used among education researchers, especially to generate hypotheses about intersectional relationships that traditional statistical analyses might not uncover.

4.2 Future Directions

Association rule mining is intended to find variables that have strong associations to each other, in order to single out patterns not obvious by simply looking at the data. Using association rule mining was an issue when analyzing uncommon or non-majority populations, and therefore uncommon categories in the dataset, because the data miner has to take the inverse of what association rule mining was constructed to do. It is for this reason that we promote new algorithms or new ways of dealing with specific-rare itemsets, keeping in mind nuanced approaches that might be easier to use for educational researchers who are not entirely familiar with data mining techniques. Also, algorithms for rule mining that are specifically tailored to analyze unlikelihood or even likelihood but in minority subsets of data within the larger dataset would be very useful for reliable results and interpretation as well as facility in usage of educational data mining techniques. Future studies could also include extending these methods to more courses with varied demographics to determine the generalizability of using association rule mining in this way.

5 CONCLUSION

We took a novel approach to uncover relationships between student variables and course success by mining these variables for association rules in order to get a better understanding of the how UR-STEM students interact with online STEM courses.

We mined for unlikely as well as likely associations. We found interesting relationships that could prompt further analysis. These findings could be beneficial to an instructor, to provide clear direction about which students need direct help or additional resources, and thereby enhance positive outcomes in a course. These findings could also prove to be beneficial to online curriculum creators as well as university policy-makers because of specific information regarding an at-risk population (first-generation and racial/ethnic minoritized students) in the leaky STEM pipeline.

ABSTRACT

In this paper, we extracted content-based and structure-based features of text to predict human annotations for claims and non-claims in argumentative essays. We compared Logistic Regression, Bernoulli Naive Bayes, Gaussian Naive Bayes, Linear Support Vector Classification, Random Forest, and Neural Networks to train classification models. Random Forest and Neural Network classifiers yielded the most balanced identifications of claims and non-claims based on the evaluation of accuracy, precision, and recall. The Random Forest model was then used to calculate the number, percentage, and positionality of claims and non-claims in a validation corpus that included human ratings of writing quality. Correlational and regression analyses indicated that the number of claims and the average position of non-claims in text were significant indicators of essay quality in the expected direction.

Keywords

argument mining, claim detection, essay quality, natural language processing, automated essay evaluation

1. INTRODUCTION

Argumentative essays include many different discourse units including a thesis statement, main ideas (claims), supporting ideas, and a conclusion (Burstein et al., 2003). Since argumentative essays are important elements in the teaching and assessment of writing, various techniques have been used to identify discourse units including those based on natural language processing (NLP). NLP has been used to automatically identify discourse elements based on the linguistic features that comprise discourse. Previous studies have found that content (i.e., lexical, syntactic, and discourse indicators) and structural features (i.e., the positionality of tokens, sentences, and paragraphs) are effective in the identification of discourse elements (Burstein et al., 1998, 2001a, 2001b, 2003; Lawrence and Reed, 2015; Nguyen and Litman, 2015, 2016; Persing and Ng, 2015; Stab and Gurevych, 2014, 2017). However, most studies have extracted content features at the word-level (unigram) or bigram level (e.g., Stab and Gurevych, 2017), or used indicators that generally occur only as transitional markers either at the beginning or the end of sentences (e.g., Burstein et al., 1998). Less is known about how multi-word n-grams (bigrams and trigrams) and their associated part-of-speech (POS) tags can influence the accuracy of discourse unit identification. Meanwhile, few if any studies, have examined how normalized positions of

sentences in paragraphs and in text can predict claims. Lastly, while some studies (e.g., Klebanov et al., 2016) have examined relations between essay quality and the use of discourse structures, these studies have examined relatively small corpora (e.g., test sets of 40 essays) and have not focused on claims, an important discourse element.

2. PURPOSE STATEMENT AND RESEARCH QUESTION

In this study, we develop NLP approaches to automatically identify claims in structurally-annotated essays using n-grams and POS tags along with positionality data. We compared the identification accuracy of the derived NLP features using different machine learning models and examined the relations between the number (and percentage) of claims and non-claims, their positionality, and human ratings of argumentative essay quality. Two structure-annotated corpora from Stab and Gurevych (2014, 2017) were used as our training ($N = 329$) and testing ($N = 90$) sets. The model with the best performance was used to identify claims and non-claims in a corpus comprising 2269 argumentative essays that had been rated on writing quality. Finally, we conducted correlation and regression analyses to explore the relations between the variables. The research questions that guide this study are as follow:

1. To what extent do (1) the frequency of n-grams (bigrams and trigrams), (2) the frequency of part-of-speech (POS) n-grams (bigrams and trigrams), and (3) positional (structural) information of sentences predict whether the sentence is a claim or not?
2. What are the relations between the number, percentage, and positionality of predicted claims/non-claims in an essay and the quality of the essay?

3. METHOD

3.1 Data

Three corpora were used in the current study. A training and testing corpora were used to train and test the claim detection algorithm, respectively. The claim detection algorithm was then applied to a validation corpus of student essays to calculate the number, percentage, and positionality of claims and non-claims in each essay. The relations of these features to claims (and non-claims) and essay quality was then examined.

3.1.1 Training set

The training corpus was developed by Stab and Gurevych (2017) and was annotated with argument components ("major claim," "claim," and "premises") and the relationships between "premises" and "major claim" or "claims" ("attack" or "support"). The corpus contains 402 argumentative essays written by students on 341 different prompts (e.g. "Will computers replace human power in jobs" and "Should students be taught to compete or cooperate").

Qian Wan, Scott Crossley, Laura Allen and Danielle McNamara "Claim Detection and Relationship with Writing Quality" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 691 - 695

The essays were collected from an online writing forum where native and non-native speakers of English could post their argumentative essays and give feedback to each other to help improve writing quality. After removing 73 essays that were duplicated in the testing set, there were 329 essays in the training corpus.

Major claims referred to sentences that directly expressed the general stance of the author that was supported by additional arguments. Claims were the central component of an argument, and premises were reasons that were provided by the author for supporting or attacking a certain claim. Three non-native annotators participated in the annotation process. According to the original study, the overall inter-rater agreement among the three annotators was .72.

3.1.2 Testing set

The testing corpus contained 90 argumentative essays compiled by Stab and Gurevych (2014). The essays were originally collected from the same source as the training set and were annotated by three annotators using the same annotation guidelines as the training set. It is unknown if the same annotators were used. The reported inter-rater reliability was .68.

3.1.3 Validation set

We selected 2269 argumentative essays written by native speakers of English as our validation corpus. The essays were collected in the development of the Writing-Pal (McNamara et al., 2012) from individual participants who composed essays in response to 13 specific prompts. Most of the participants were students ranging in grade levels from 7th to 10th or first-year college students. The participants were asked to respond to a specific prompt, state the degree to which they agreed or disagreed with the statement, and provide supporting evidence and arguments to persuade the readers. The essays in the validation corpus were evaluated by human raters following the scoring rubric used in the SAT (a standardized test used for college admittance in the United States). The SAT rubric evaluated writing in terms of ideas, organization, style, and voice. Raters were asked to assign each essay a quality score between 0-6. Interrater-reliability was greater than Cohen's Kappa .60 and r .70. Averages were taken between the two raters. If two raters disagreed by greater than one point on the 6-point scale, they were asked to adjudicate the essay. The average score for the essays was 3.38 and the standard deviation was .91.

3.2 Algorithm Development

Data preprocessing, feature development, application of machine learning models, and the selection of those models were the four major steps in the development of the classification algorithms for the claims and non-claims. We report the first two major steps in the following section and report the application and selection of machine learning models in the results section.

3.2.1 Merge and build standardized structure-annotated sub-corpora

The training and testing corpus were annotated using a framework of three argumentative units ("major claim," "claim," and "premise"). However, in this study we are only interested in distinguishing claims from non-claims. Based on our focus, we merged the tags of "major claim" and "claim" and treated both of them as a larger category of claim. We treated any sentences in an essay that did not fall into the category of claim as a non-claim. We

then unified the formats of the two structural annotated corpora by tokenizing the essays into sentence and adding structural tags (claim or non-claim) for each sentence based on the annotation of the original corpora. Further, we extracted all claim sentences from the training corpus to build the claim sub-corpus and extracted all the non-claim sentences to build the non-claim sub-corpus.

3.2.2 N-gram and n-gram POS tokenization

In this study, all of the n-gram and POS n-gram features for model development were extracted only from the training corpus. After the claim and non-claim sub-corpora were built, a Python script was written to tokenize the sentences within each corpus into bigrams and trigrams. Thus, all of the n-grams were extracted on sentence instead of clause levels. Prior to n-gram tokenization, all punctuations within the sentences were removed. Then, all of the characters were set to lowercase and all extra blanks in the sentences were removed from the texts. Stop words (e.g., *of*, *a*, *and*, *the*) were not deleted from the text. The texts were not lemmatized or stemmed.

We used the NLTK (Natural Language Toolkit; Bird et al., 2009) to tokenize the claim and non-claim sub-corpora into bigram and trigram. After the n-gram tokenization, we used the NLTK part-of-speech tagger to label the word class of each word within each sentence in the claim and non-claim sub-corpora. The NLTK pos-tagger labels part-of-speech for each word based on Penn Treebank tagset (Marcus et al., 1993). Prior studies have shown that the overall accuracy of NLTK pos-tagger was 91.33% for Brown Corpus, 89.56% for Treebank Corpus, and 86.45% for NPS Chat Corpus (Yumusak et al., 2014). Once the POS-tagging was completed, we used the NLTK tokenizer to segment the POS-tagged corpora into part-of-speech bigrams and trigrams. For example, the following phrases *should be*, *would be*, *can be*, and *will be* would be converted to the same POS n-gram combination: MD (modal) + VB (verb base).

3.2.3 Normalized frequency and Keyness values

We calculated raw frequency and normalized frequency for each bigram, trigram, as well as POS bigram and trigram term in the training corpus (both claim and non-claim sub-corpora). In addition to raw and normalized frequency, keyness value of each n-gram and POS n-gram was also calculated based on the raw frequency data. Keyness value, based on log-likelihood values, provided evidence of whether n-grams and POS n-grams were more common in one corpus compared with the other corpus (Kilgariff, 2001).

The thresholds for log-likelihood was 3.84 (equivalent to $p < .05$). Specifically, for any n-gram or POS n-gram that appeared in both corpora, if the n-gram or POS n-gram had a log-likelihood value greater than 3.84, we considered it more likely to occur in one corpus over the other. In this study, we wrote a Python script to automatically calculate the Keyness values (log-likelihood values) for all n-grams or POS n-grams that could be found in both claim and non-claim sub-corpora based on Rayson and Garside (2000). In Table 1, we list the top n-grams and POS n-grams with highest keyness values found in claims and non-claims.

In total, we calculated the following indices in the training, testing, and validation corpus, respectively: (1) the frequency of significant n-grams (bigrams and trigrams) in the claims extracted from the training corpus in each sentence; (2) the frequency of significant n-grams in the non-claims extracted from the training corpus in each sentence; (3) the frequency of significant POS n-grams in the claims in each sentence; and (4) the frequency of significant POS

n-grams in the non-claims in each sentence. In this way, for each sentence in each corpus, we derived eight indices.

Table 1 Top n-grams with highest keyness values in claims and non-claims

3.2.4 Positional data for sentences

Beyond n-gram patterns, studies have shown that in argumentative or academic writing, sentence position is an indicator of the structural function of the sentence (e.g., Burstein et al., 1998, 2001a; Biber et al., 2004). In this study, the following raw and normalized positional variables for each sentence in an essay were calculated as potential positional features: (1) the position of the sentence in the whole essay (e.g., if a sentence is the 5th sentence in the essay, the value of this variable would be 5); (2) normalized sentence position in the essay (i.e., equal to the value in [1] divided by the total number of sentences in the essay); (3) the position of the paragraph in which the sentence was located (e.g., if the sentence occurred in the 2nd paragraph of the essay, this value would be 2); (4) normalized paragraph position in the essay (i.e., equal to the value in [2] divided by the total number of paragraphs in the essay); (5) the position of the sentence in the paragraph where the sentence occurred (e.g., if the sentence was the 4th sentence in its paragraph, the value would be 4); and (6) the normalized position of a sentence in a paragraph (i.e., equal to the value in [5] divided by the total number of sentences in the paragraph).

3.3 Validation Study

Our second objective was to examine the relationship of the number/percentage of claims and positional data with the quality (human score) of the essay. To do so, the algorithm (from the final model) to predict the discourse type (claim or non-claim) was applied to each sentence of each essay in the validation corpus. We then calculated the percentages and average position of claim and non-claim sentences in each essay of the validation corpus and used these features to model essay quality to examine the following: (1) correlations between essay quality (represented by human holistic scores of the essays) and the number/percentage and positionality of claims/non-claims in the essay; and (2) the extent to which the number and percentage of claims/non-claims in an essay and sentence positionality predict its quality. In the regression analysis, the number of claims, the number of non-claims, the percentage of claims, the percentage of non-claims in an essay, and sentence positionality were included as the independent variables, while the human score of the essay served as the dependent variable. Prior to analyses, the human scores were checked for normality; multicollinearity ($r < .70$) across all independent variables was checked to ensure the variables developed were unique.

4. RESULTS

In the following sections, we report the results for feature selection, machine learning model selection, and the statistical analyses.

4.1 Feature Selection

As we have reported in the method section, we applied both content-based features and structure (position) based features to train the model.

Altogether, we had 17 features calculated at the sentence level. Six were structure (position) based features as reported in the method section: (1) the position of the sentence in the whole essay; (2) normalized sentence position in the essay; (3) the position of the paragraph in which the sentence was located; (4) normalized paragraph position in the essay; (5) the position of the sentence in the paragraph where the sentence occurred; and (6) the normalized position in paragraph. Eight of the features were content-based n-gram/POS n-gram frequency calculated based on sentence level. These features included: (1) the frequency of significant bigrams in claims; (2) the frequency of significant bigrams in non-claims; (3) the frequency of significant POS bigrams in claims; (4) the frequency of significant POS bigrams in non-claims; (5) the frequency of significant trigrams in claims; (6) the frequency of significant trigrams in non-claims; (7) the frequency of significant POS trigrams in claims; and (8) the frequency of significant POS trigrams in non-claims. The other three features were word counts, bigram counts, and trigram counts of the sentence.

Before moving forward to build the model, we conducted correlational analyses to remove highly correlated variables. The results of this analysis indicated that the position of the sentence in the essay was highly correlated with normalized sentence position in the essay ($r = .85, p < .001$), with the position of paragraph in essay ($r = .91, p < .001$), and with normalized paragraph position in essay ($r = .83, p < .001$). Normalized sentence position in essay was also highly correlated with the position of the paragraph in essay ($r = .89, p < .001$) and normalized paragraph position in essay ($r = .94, p < .001$). Meanwhile, the position of paragraph in essay was highly correlated with normalized paragraph position in essay ($r = .92, p < .001$). Based on these results, we decided to remove the position of sentence in essay, the paragraph position in essay, and the normalized paragraph position from the independent variables.

For the structure-based features, only the frequency of significant POS trigrams had a strong correlation with the frequency of significant POS bigram ($r = .54, p < .001$). For the word and n-gram counts variables, since the variable word counts were highly correlated with bigram counts ($r = 1, p < .001$) and trigram counts ($r = 1, p < .001$), we decided to remove both of the latter variables and only keep the variable of word counts. After this process, 10 features remained for model development (see Table 2).

Table 2 Summary of structural and content-based features for model development

Category	Feature
Structure (positional) features	Normalized sentence position in the essay
	Normalized sentence position in the paragraph
Content-based features	Word counts of the sentence
	The frequency of significant bigrams in claims in the sentence
	The frequency of significant bigrams in non-claims in the sentence
	The frequency of significant POS bigrams in claims in the sentence
	The frequency of significant POS bigrams in non-claims in the sentence
	The frequency of significant trigrams in claims in the sentence
	The frequency of significant trigrams in non-claims in the sentence
	The frequency of significant POS trigrams in claims in the sentence

4.2 Model Selection

We built six different supervised machine learning models on our training data using six different classifiers. We then we used the six models to predict discourse types of sentences in our testing corpus. We evaluated the performance of the models using accuracy, precision, recall, and F1-score. Table 3 reports the performance of the classifiers on claim and non-claim identification in the test set. The Random Forest model was selected as the best model to predict the discourse type in the validation corpus.

Table 3 Performance of the multiple classifiers on claim detection in the test set

		TP	TN	FP	FN	Precision	Recall	F1-score	Accuracy
LR	Claim	347	629	445	161	0.44	0.68	0.53	0.62
	Non-claim	629	347	161	445	0.80	0.59	0.67

4.3 Relationship between Essay Quality and Number of Claims

Spearman's correlations were computed among the number, percentage, and the average positionality of claims and non-claims and the human raters' holistic scores for each essay in the validation corpus. We included text length to assess if the raw scores highly correlated with the number of words in the essay (a strong predictor of essay quality). Correlational analysis indicated the number of predicted claims ($r = .35, p < .001$) and the average position of non-claims in text ($r = -.19, p < .001$) showed at least a small effect size ($r > .099$) with essay quality and were not strongly correlated with text length ($r < .70$). These variables were selected for inclusion in our regression analysis to predict essay quality scores. However, the percentage of predicted claims ($r = .08, p = .015$) and non-claims ($r = -.08, p = .015$) and the average position of claims ($r = .04, p < .001$) had weak correlations with essay quality.

A significant regression equation was reported ($R^2 = .132, F(2,2266) = 172.3, p < .001$). The model explained 13.2% of the variance of the human scores. Two significant predictors of essay quality were included in the model: number of claims ($\beta = .132, p < .001$) and the average position of non-claims in text ($\beta = -2.829, p < .001$).

5. CONCLUSION AND FUTURE WORK

In this study, we extracted content-based linguistic features and structure-based features to train and predict discourse types of claim and non-claim in argumentative essays. The average testing accuracy (F1) of the classifiers used in this study (Logistic Regression, Bernoulli Naive Bayes, Gaussian Naive Bayes, Linear

Support Vector Classification, Random Forest, and Neural Network) was around .69. This aligns with the accuracies reported in Stab and Gurevych (2017) to a degree. In their work, they reported F1 scores from an SVM classifier for major claims, claims, and premises using structural, lexical, contextual, syntactic, discourse markers, and embeddings features. Their F1 scores for these features in tandem were .77. F1 scores in isolation were .59 for lexical features, .60 for contextual features, .39 for syntactic features, .52 for discourse features, and .75 for structural features. These results seem to indicate that the individual content-based features (lexical, syntactic, indicator, and contextual features) might have encountered an upper limit in terms of the accuracy of identification if other features were not combined. The accuracy of the identification of claims in our study also seems to support this interpretation.

In terms of application, we found that the number of claims and the average position of non-claims in text were indicators of essay quality. A significant regression model was found to predict holistic human scores based on these variables. The model explained 13% of the variance in the human scores.

To improve the accuracy of classification, we are planning to implement a classifier with more diverse features from a contextual and discourse perspective including contextual, discourse, syntactic, and lexical features. We presume this will increase accuracy based on findings from Stab and Gurevych (2017) who showed that the combination of all features increased their accuracy. We also intend to investigate the relationship between argumentation elements from a broader view by including more argumentation elements such as major claims, primary claims, counterarguments, rebuttals, and conclusions. Further, we plan on annotating the relationships between these discourse elements and build models to automatically identify the discourse elements as well as their functional relationships.

In the current study, we have demonstrated the usefulness of content and structural features in automated claim detection and explored the relations between the number and positionality of claims and writing quality. Our findings can positively supplement existing automated essay scoring (AES) and automated writing evaluation (AWE) systems and may provide implications for the teaching of argumentative essays.

ABSTRACT

We propose VarFA, a variational inference factor analysis framework that extends existing factor analysis models for educational data mining to efficiently output uncertainty estimation in the model’s estimated factors. Such uncertainty information is useful, for example, for an adaptive testing scenario, where additional tests can be administered if the model is not quite certain about a students’ skill level estimation. Traditional Bayesian inference methods that produce such uncertainty information are computationally expensive and do not scale to large data sets. VarFA utilizes variational inference which makes it possible to efficiently perform Bayesian inference even on very large data sets. We use the sparse factor analysis model as a case study and demonstrate the efficacy of VarFA on both synthetic and real data sets. VarFA is also very general and can be applied to a wide array of factor analysis models. Code and instructions to reproduce results in this paper are available at <https://tinyurl.com/tvm4332>. An extended version of this paper is available at <https://arxiv.org/abs/2005.13107>.

1. INTRODUCTION

A core task for many practical educational systems is *student modeling*, i.e., estimating students’ mastery level on a set of skills or knowledge components (KC) [14, 6]. Such estimates allow in-depth understanding of students’ learning status and form the foundation for automatic, intelligent learning interventions. A fruitful line of research for student modeling follows the *factor analysis (FA)* approach. FA models usually assume that an unknown, potentially multi-dimensional student parameter, in which each dimension is associated with a certain skill, explains how a student answers questions and is to be estimated.

Most of the aforementioned FA models compute a single point estimate of skill levels for each student [13, 1, 3, 9, 5, 15]. Often, however, it is not enough to obtain mere point estimates of students’ skill levels; knowing the model’s uncertainty in its estimation is crucial because it potentially

helps improve the model’s performance and improve both students’ and instructors’ experience with educational systems. For example, in adaptive testing systems [4, 16], knowing the uncertainty in model’s estimation could help the model intelligently pick the next test items to most effectively reduce its uncertainty about estimated students’ skill levels. This will help to potentially reduce the number of items needed to have a confident, accurate estimation of the students’ skill mastery level, saving time for both students to take the test and instructors to have a good assessment of the student’s skills.

In this work, we propose VarFA, a novel framework based on *variational inference* (VI) to perform efficient, scalable Bayesian inference for FA models. The key idea is to approximate the true posterior distribution, whose costly computation slows down Bayesian inference, with a *variational distribution*. In addition, this variational distribution is very flexible and we have full control specifying it, allowing us to freely use the latest development in machine learning, e.g., deep neural networks (DNNs), to design the variational distribution that closely approximates the true posterior. Thus, we also regard our work as a first step in applying DNNs to FA models for student modeling, achieving efficient Bayesian inference (enabled by DNNs) without losing interpretability (brought by FA models). We demonstrate the efficacy of our framework on three real data sets, showcasing that VarFA substantially accelerates classic Bayesian inference for FA models with no compromise on performance.

2. BACKGROUND

We first set up the problem and review related work. Assume we have a data set $\mathbf{Y} \in \mathbb{R}^{N \times Q}$ organized in matrix format where N is the total number of students and Q is the number of questions. This is a binary students’ answer record matrix where each entry y_{ij} represents whether student i correctly answered question j . Usually, not all students answer all questions. Thus, \mathbf{Y} contains missing values. We use $\{i, j\} \in \Omega_{\text{obs}}$ to denote entries in \mathbf{Y} , i.e., the i -th student’s answer record to the j -th question, that are observed.

We are interested in models capable of inferring each i -th student’s skill mastery level that can accurately predict the student’s answers given the above data. These models are often evaluated on the prediction accuracy and whether the inferred student skill mastery levels are easily interpretable and educationally meaningful. We now review factor anal-

"VarFA: A Variational Factor Analysis Framework For Efficient Bayesian Learning Analytics" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 696 - 699

ysis models (FA), one of the most widely adopted and successful methodologies for the student modeling task.

Many FA models, despite differences in their respective mathematical formulae, modeling assumptions and the available auxiliary data used, can be unified into a canonical formulation below

$$\mathbb{P}(y_{ij} = 1) = \sigma(\mathbf{c}_i^\top \mathbf{m}_j + \mu_j), \quad (1)$$

where $\mathbf{c}_i \in \mathbb{R}^K$, $\mathbf{m}_j \in \mathbb{R}^K$ and $\mu_j \in \mathbb{R}$ are factors whose dimension, interpretations and subscript indices depend on the specific instantiations of the FA model. We will use this general formulation in the rest of this paper. Usually, FA models obtains a point estimate of \mathbf{c}_i , \mathbf{m}_j and μ_j . We will show next how to obtain uncertainty estimation of these variables of interest.

3. VARFA: A VARIATIONAL INFERENCE FACTOR ANALYSIS FRAMEWORK

The core idea of VarFA follows the variational principle, i.e., we use a parametric variational distribution to approximate the true posterior distribution. VarFA is highly flexible and efficient, making it suitable for large scale Bayesian inference for FA models in the context of educational data mining. In this current work, we focus on obtaining credible interval for the student skill mastery factor \mathbf{c}_i 's as a first step of VarFA. Extension to VarFA to full Bayesian inference for all unknown factors is part of an ongoing research; see 5 for more discussions.

Now, we explain in detail how to apply variational inference for FA models for efficient Bayesian inference. Because the posterior distribution is intractable to compute, we approximate the true posterior distribution for \mathbf{c}_i 's with a parametric variational distribution

$$p(\mathbf{C}|\mathbf{Y}, \mathbf{M}, \boldsymbol{\mu}) \approx q_\phi(\mathbf{C}|\mathbf{Y}) = \prod_{i=1}^N q_\phi(\mathbf{c}_i|\mathbf{y}_i), \quad (2)$$

where ϕ is a collection of learnable parameters that parametrize the variational distribution and \mathbf{y}_i is all the answer records by student i . Notably, we have removed the dependency of the variational distribution on ψ and θ so that the variational distribution is solely controlled by the variational parameter ϕ . Thus, the design of the variational distribution is highly flexible. All we need to do is to specify a class of distributions and design a function parametrized by ϕ to output the parameters of q_ϕ . Common in prior literature is to use a Gaussian with diagonal covariance for q_ϕ :

$$q_\phi(\mathbf{c}_i|\mathbf{y}_i) = \mathcal{N}(\mathbf{u}_i, \text{diag}(\mathbf{v}_i)), \quad (3)$$

where its mean and variance $[\mathbf{u}_i^\top, \mathbf{v}_i^\top]^\top = f_\phi(\mathbf{y}_i)$. We can use arbitrarily complex functions such as a deep neural network for f_ϕ as long as they are differentiable. With the above approximation, Bayesian inference turns into an optimization problem under the variational principle, where we now optimize a lower bound, known as the evidence lower bound (ELBO) [2], of the marginal data log likelihood.

We form the following optimization objective to estimate ϕ

where $\theta = \{\mathbf{m}_1, \dots, \mathbf{m}_Q, \mu_1, \dots, \mu_Q\}$ and $\mathcal{R}(\theta)$ is a regularization term. That is, we perform VI on the student factor \mathbf{c}_i 's and MLE inference on the remaining factors denoted as θ .

4. EXPERIMENTS

We demonstrate the efficacy of VarFA variational inference framework using the sparse factor analysis model (SPARFA-M) as the underlying FA model. On three real-world data sets, we demonstrate that 1) VarFA predicts students' answers more accurately than SPARFA-M; 2) VarFA can output the same insights as SPARFA-M, including point estimate of students' skill levels and questions' associations with skill tags; 3) VarFA can additionally output meaningful uncertainty quantification for student skill levels, which SPARFA-M is incapable of, without sacrifice to computational efficiency. Note that SPARFA-B can also compute uncertainty for small data sets but fails for large data sets due to scalability issues and thus we do not compare to SPARFA-B for real data sets. The code along with instructions to reproduce our experiments can be downloaded from <https://tinyurl.com/tvm4332>.

Data sets. We perform experiments on three large-scale, publicly available, real educational data sets including AS-

Figure 1: Violin plot showing the mean and standard deviation of the estimated skill mastery levels on 10 selected students on the 3rd, 4th and 7th latent skills that VarFA computes. In each sub-figure, bottom and top axes respectively shows student IDs and top axis shows the number of questions each student answered.

SISTments 2009-2010 (Assistment) [7], Algebra I 2006-2007 (algebra) [10] and Bridge to Algebra 2006-2007 (bridge) [11, 12]. The details of the data sets, including data format and data collection procedure can be found in the preceding references.

Results: Performance Comparison. Table 1 shows the average performance on the test set of each data set comparing VarFA and SPARFA-M for all three data sets and additionally run time. We can see that VarFA achieves slightly better student answer prediction on most data sets and on most metrics. Table 1 also shows the run time comparison between VarFA and SPARFA-M; see the last row in each sub-table. We see that both inference algorithms have very similar run time, showing that VarFA is applicable for very large data sets. Notably, VarFA achieves this efficiency while also performing Bayesian inference on the student knowledge level factor.

Results: Bayesian Inference With VarFA. We now illustrate VarFA’s capability of outputting credible intervals using the Assistment data set. Fig. 1 presents violin plots that show the sampled student latent skill levels for a random subset of 10 students. Plots 1a, 1b and 1c shows the inferred students ability for the 3rd, 4th and 7th latent skill dimension. In each plot, the bottom axis shows the student ID and the top axis shows the total number of questions answered by the corresponding student. For each student, the horizontal width of the violin represents the density of the samples; the skinnier the violin, the more widespread the samples are, implying the model’s less certainty on its estimations.

Results in Fig. 1 confirms our intuition that the more questions a student answers, the more certain the model is about its estimation. For example, students with ID 106, 110 and 389 answered 222, 181 and 149 questions, respectively, and the credible intervals of their ability estimation is quite small. In contrast, students with ID 27, 49 and 65 answered far less questions and the credible intervals of their ability estimation is quite large. This result implies that VarFA outputs sensible and interpretable credible intervals.

Results: Post-Processing for Improved Interpretability.

SPARFA assumes that each student factor \mathbf{c}_i identifies a multi-dimensional skill level on a number of “latent” skills (recall that we use 8 latent skills in our experiments). As mentioned earlier, these latent skills are not interpretable without the aid of additional information. To improve interpretability, [8] proposed that, when the skill tags for each question is available in the data set, we can associate each latent skill with skill tags via a simple matrix factorization. Then, we can compute each students’ mastery levels on the actual skill tags.

We again use the Assistment data set for illustration. We compute the association of skill tags in the data set with each of the latent skills and show 4 of the latent skills with their top 3 most strongly associated skill tags. We can see that each latent skill roughly identify the same group of skill tags. For example, latent skill 4 clusters skill tags on statistics and probability while latent skill 7 clusters skill tags on geometry. Thus, by simple post-processing, we obtain an interpretation of the latent skills by associating them with known skill tags in the data.

We can similarly obtain VarFA’s estimations of the students’ mastery levels on each skill tags through the above process. In Fig. 2, we compare the predicted mastery level for each skill tag (only for the questions this student answered) with the percent of correct answers for that skill tag. Blue curve shows the empirical student’s mastery level on a skill tag by computing the percentage of correctly answered questions belonging to a particular skill tag. Orange curve shows VarFA’s estimated student mastery level on a skill tag, normalized to range [0, 1]. Even though the two curves show different numeric values, they nevertheless demonstrate similar trends, showing that the predictions reasonably match our intuition about student’s skill mastery levels.

5. CONCLUSIONS AND FUTURE WORK

We have presented VarFA, a variational inference factor analysis framework to perform efficient Bayesian inference for learning analytics. VarFA is general and can be applied to a wide array of FA models. We have demonstrated the effectiveness of our VarFA using the sparse factor analysis (SPARFA) model as a case study. We have shown that VarFA can very efficiently output interpretable, education-

Table 2: Illustration of the estimated latent skills with the their top 3 most strongly associated skill tags in the Assistentment data set. The percentage in the parenthesis shows the association probability (summed to 1 for each latent skill). We see that the tagged skills associated with each estimated latent skill form intuitive and interpretable groups.

Latent Skill 1	Latent Skill 3
Division Fractions (29.1%) Least Common Multiple (18.1%) Write Linear Equation from Ordered Pairs (17.8%)	Conversion of Fraction Decimals Percents (7.3%) Addition and Subtraction Positive Decimals (6.8%) Probability of a Single Event (5.7%)

ally meaningful information, in particular credible intervals, much faster than classic Bayesian inference methods. Thus, VarFA has potential application in many educational data mining scenarios where efficient credible interval computation is desired, i.e., in adaptive testing and adaptive learning systems. We have also provided open-source code to reproduce our results and facilitate further research efforts.

ABSTRACT

As students progress in their university programs, they have to face many course choices. It is important for them to receive guidance based on not only their interest, but also the “predicted” course performance so as to improve learning experience and optimise academic performance. In this paper, we propose the next-term grade prediction task as a useful course selection guidance. We propose a machine learning framework to predict course grades in a specific program term using the historical student-course data. In this framework, we develop the prediction model using Factorization Machine (FM) and Long Short Term Memory combined with FM (LSTM-FM) that make use of both student and course attributes as well as past student-course grade data. Our experiment results on a real-world data of an autonomous university in Singapore show that both methods yield better prediction accuracy than the baseline methods. Our methods are also robust to handle cold start courses with the average prediction error can be as low as three quarter grade difference from the ground truth.

Keywords

Grade prediction, factorization machine, long short term memory

1. INTRODUCTION

Predicting student grades has recently gained attention as it benefits not only students, but also instructors [3]. Students face many course courses in every new term. They need some guidance based on their “predicted” performance in future courses so as to improve their course selection and overall academic performance. Instructors, on the other hand, can also adjust their course delivery methods to the predicted student grade performance.

We consider a university setting where students are required to choose courses at the beginning of each program term.

Audrey Tedja Widjaja, Lei Wang, Nghia Trong Truong, Aldy Gunawan and Ee-Peng Lim "Next-Term Grade Prediction: A Machine Learning Approach" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 700 - 703

The predicted grades of the selected courses is then evaluated against the grades received at the end of that term. This task is called the *next-term student grade prediction* and it requires the past student-course grade data to provide useful features to predict grades of courses taken in the following term.

Our next-term student grade prediction task is different from the previous student grade prediction works [2, 3] which focused on predicting grades of a calendar term where students from different admission years are predicted together. Since different program terms are included in the prediction task, it is difficult to train the model to specialize on courses in the specific program term of the students.

In this paper, we develop FM and long short term memory combined with FM (LSTM-FM) models that are trained on student’s program terms instead of calendar terms. The proposed models are evaluated on a real-world data collected from an autonomous university in Singapore. We further make use of both static and dynamic student and course attributes to derive features that improve the prediction results. Additionally, our proposed models could perform well on predicting both existing and cold-start courses.

2. PROBLEM FORMULATION

Given a set of students $S = \{s_1, s_2, \dots, s_{|S|}\}$, where each student belongs to a certain cohort, denoted by $cohort(s_i)$ (i.e. batch of students admitting to the university in the same year). To graduate from their programs, students must complete $T = \{t_1, t_2, \dots, t_{|T|}\}$ program terms and register one or more courses in each program term. Let $C = \{c_1, c_2, \dots, c_{|C|}\}$ be the set of all courses taken by students from S . We denote the grade obtained by student s_i in course c_j by $g_{i,j} \in \{A+, A, \dots, F\}$. Our task is then to predict $g_{i,j}$ for every student s_i from a target student cohort S in a target program term t_k for every course students have registered in the program term t_k . We assume that the course grades for earlier program term(s) by the same students are available, and the course grades for students from previous cohorts in the earlier and target terms can be observed.

We define the feature representation of a student-course pair (s_i, c_j) as a feature vector $X_{i,j}$. A prediction model for the above problem is thus a function $F: X \rightarrow Y$ where $Y \in \mathbb{R}^2$. F is learned from a training data (t_k, X^{trg}, Y^{trg}) . For each

	Cohort 1	Cohort 2	Cohort 3	Cohort 4
Program term 1	Y^{trg}			Y^{test}

	Cohort 1	Cohort 2	Cohort 3	Cohort 4
Program term 1	X^{trg}			X^{test}
Program term 2	Y^{trg}			Y^{test}

	Cohort 1	Cohort 2	Cohort 3	Cohort 4
Program term 1	X^{trg}			X^{test}
Program term 2				
Program term 3	Y^{trg}			Y^{test}

Figure 1: Training and testing instances for program term-specific grade prediction involving data from cohorts 1 to 3 as training, and data from cohort 4 as test.

student $s_i \in S$, $Y_{i,j}^{trg}$ is unknown for courses c_j 's registered by s_i during the target program term t_k . For each student s_i of earlier cohorts, $Y_{i,j}^{trg} = g_{i,j}$ for courses c_j 's registered by s_i in the target program term t_k . For all students, $X_{i,j}^{trg}$ are features derived from student s_i and course c_j using data from earlier program terms. The testing data $(t_k, X^{test}, Y^{test})$ consists of $X_{i,j}^{test} = X_{i,j}^{trg}$ and $Y_{i,j}^{test} = g_{i,j}$ when s_i received the grade $g_{i,j}$ in the program term t_k .

Figure 1 illustrates the training and testing instances of the next term grade prediction for students of cohort 4 in target program terms 1 to 3. For target program term 3 (see the last table of the figure), the training data include the student-course data of students from cohorts 1 to 3. The feature representation of a student-course pair is derived from program terms 1 to 2 of these students, or from the non-program term student and course attribute data (e.g., student education background, course major, etc.).

This program term-specific grade prediction approach is more intuitive than previous works that focused on the grade prediction for students taking courses in the same calendar term which could involve different program terms for students from different cohorts [2, 3]. Since student grades of different program terms refer to different sets of courses, our problem definition and solution approach ensure that dyad features and ground truth labels for the testing data of a target program term follow the same data distribution as that of the training data.

3. DATASET AND FEATURES

3.1 Dataset Description

The dataset was collected from an autonomous university in Singapore that covers four consecutive cohorts (2011- 2014) of undergraduate students from the same degree program. Students are required to complete 8 program terms.

Table 1 shows the dataset statistics. It consists of 618 students and 691 courses. In total, we have 19,655 student-course pairs that involve grades, known as the student-course dyads. Students from cohort 4 are used as the test cohort to allow more data to be used in training. The university implements 12 grading letters that are mapped to numeric values for grade prediction as follows. A+, A, A-, B+, B, B-, C+, C, C-, D+, D, and F are mapped to 4.3, 4.0, 3.7, 3.3, 3.0, 2.7, 2.3, 2.0, 1.7, 1.3, 1.0, and 0.0 respectively.

Table 1: Dataset Statistics

	Cohorts				Total
	1	2	3	4	
Num. Students	115	145	157	201	618
Num. Courses	169	160	170	192	691
Num. Dyads	3748	4471	4850	6586	19,655

Table 2: Student-Course Dyads of Target Cohort 4 (CSS: cold start students, CSC: cold start courses, NCS: non-cold start dyads)

Program term	#dyads	#NCS	CS	
			#CSC	#CSS
t_1	986	0	0	986
t_2	955	952	3	0
t_3	856	850	6	0
t_4	919	907	12	0
t_5	801	789	12	0
t_6	704	677	27	0
t_7	699	676	23	0
t_8	666	638	28	0

Cold start dyads. The cold start student-course dyads of a target program term are ones with new students or courses with respect to the program term. They do not appear in the training set, but appears in the testing set. As shown in Table 2, program term t_1 sees all cold start dyads with new students (denoted by CSS). The other program terms however hardly encounter new students. Dyads involving cold start/new courses (denoted by CSC) are relatively fewer as not many new courses are introduced in each program term. Most of the new courses are observed in the program terms t_6 to t_8 , the last 3 terms of the program. The other dyads are the non-cold start (NCS) dyads.

3.2 Student-Course Features

We consider five categories of features for representing the student-course dyads (s_i, c_j) :

Static student features. These are features of a student which do not change with time as they are not associated with any target program term, such as student's *major*, *gender*, *alma_mater*, and *cohort*.

Dynamic student features. These are student features derived from the data and their values may vary in different target program terms. These features are particularly useful to determine the latest performance and academic load of the student, such as student's average grade in the previous program term (*lterm_gpa*) and up to previous program term (*lterm_cum_gpa*), number of credit units (CUs) a student received up to previous program term (*total_chrs*) and registered in the target program term (*term_chrs*), average CUs per program term taken by a student (*speed*), number of courses taken by a student in every course discipline up to target program term (*disc_distrib*), relative CUs gained by a student compared to all students in the same cohort (*rel_total_chrs*), and relative *lterm_cum_gpa* of a student compared with that of the cohort (*rel_lterm_cgpa*).

Static course features. These are features of a course c_j that do not change with time: course's discipline (*disc*), CUs (*chrs*), and level (*clevel*).

Dynamic course features. These are features of a course c_j that change with time: instructor of c_j (*iid*), number of students taking c_j in the target program term (*num_enrolled*) and in all previous program terms (*total_enrolled*), average grade (*term_cgrade*) and grade distribution (*term_dgrade*) obtained by students of the previous cohort when they took c_j in the target program term, average grade (*lterm_cum_cgrade*) and grade distribution (*lterm_cum_dgrade*) obtained by students of the same and previous cohorts when they took c_j in any program terms in the past.

Student-course interaction features. As we know which student s_i takes which course c_j in the target program but not the grade, we can exploit this information to derive some features that capture the *indirect* interaction between s_i and c_j for us to determine if s_i will perform well in c_j . We derive *rel_ctype* that measures the program term s_i registered for c_j relative to the program term other students of the same cohort taking c_j . We also derive *disc_grade* which is the average grade obtained by s_i when taking any courses sharing the same course discipline as c_j in the previous terms.

4. PROPOSED METHODS

Two methods are proposed for the next-term grade prediction task, namely, **Factorization Machine (FM)**, and **Integrated Long and Short Term Memory with FM (LSTM-FM)**. The former is often used for recommendation tasks. The latter is a sequence model combined with FM to predict grades of courses in each program term.

4.1 Factorization Machine (FM)

To use FM for next-term grade prediction, our training data for predicting grades in a target term t_k is represented by a $N_{trg}^{dyads} \times p$ matrix, X , where N_{trg}^{dyads} represents the number of training dyads, $p = |S| + |C| + |F|$, and F represent the set of features. Each row $X(i, j)$ for dyad (s_i, c_j) consists of a one-hot vector of student ids, a one-hot vector of course ids, and the features representing the dyad (s_i, c_j) .

Model. FM captures both 1-way and 2-way interactions between all features using factorized interaction parameters, as formulated below.

$$\hat{Y}_{i,j} = w_0 + \sum_{k=1}^p w_k X_{i,j,k} + \sum_{k=1}^p \sum_{k'=1}^p X_{i,j,k} X_{i,j,k'} \sum_{f=1}^k v_{k,f} v_{k',f}$$

where w_0 captures the global intercept and together with the $\sum_{k=1}^p w_k X_{i,j,k}$ serves as a basic linear regression model. The last part contains all pairwise interactions of the X features, which is modeled as a factorized parameterization $\sum_{f=1}^k v_{k,f} v_{k',f}$.

4.2 LSTM-FM Model

In LSTM-FM, we merge a sequence model with FM to both learn the sequence of grades received by a student and predict the grades in the target program term using the observed sequence as well as the feature interaction for the student-course dyads. The LSTM-FM framework (Figure 2) is decomposed into two main components: 1) *Input Layer* that utilizes bidirectional LSTM networks (Bi-LSTM) [1] to model the historical grades of a student and 2) *Interaction Layer* that employs interaction module similar to FM in order to model features interactions. The returned value is

Figure 2: LSTM-FM framework

then transformed into the predicted grade by using 2-layer feed-forward networks with layer normalization [4].

As there can be a number of courses taken by the student in the same program term, we define $G_{t_k, c_j}^{s_i}$ as a $|C|$ dimensional vector keeping the grade score of student s_i gets for course c_j in program term t_k . We then use historical courses-grades of student s_i , $G_{t_k, c_j}^{s_i}$'s, for terms t_1, \dots, t_{k-1} to learn the hidden states using Bi-LSTM. We subsequently concatenate the hidden states $\vec{h}(s_i, t_{k-1})$ and $\vec{h}(s_i, t_{k-1})$ of the bi-LSTM into $h(s_i, t_{k-1})$ which is fed to the interaction layer with the (s_i, c_j) 's features to predict $G_{t_k, c_j}^{s_i}$.

5. EXPERIMENTS

5.1 Evaluation Metrics

Root mean squared error (RMSE) and mean absolute error (MAE) are used to evaluate the accuracy of different grade prediction methods as formulated below. The grades need to be converted to numerical values before using the two metrics. For both RMSE and MAE, the error is defined by the difference between the predicted grade and the actual grade. RMSE is appropriate to penalize methods that yield large errors. MAE, on the other hand, provides the average difference between the predicted and actual grades. For example, for a given actual grade of A- (with numeric score = 3.7), an MAE of 0.3 suggests that the predicted grade differs from the actual grade by an average of half grade, say B+ (with score = 3.4) or A (with score = 4.0).

$$RMSE = \sqrt{\frac{\sum_{Y_{i,j}^{trg} \text{ is defined}} (\hat{Y}_{i,j}^{test} - Y_{i,j}^{test})^2}{|\{(i, j) | Y_{i,j}^{trg} \text{ is defined}\}|}}$$

$$MAE = \frac{\sum_{Y_{i,j}^{trg} \text{ is defined}} |\hat{Y}_{i,j}^{test} - Y_{i,j}^{test}|}{|\{(i, j) | Y_{i,j}^{trg} \text{ is defined}\}|}$$

5.2 Methods for Evaluation

We focus on evaluating FM and LSTM-FM with the features defined in Section 3. There are several variants for both depending on what features are used: FM and LSTM-FM without any features other than student id and course id are also included (**FM and LSTM-FM without features**),

Table 3: Overall Results (CSC: Cold Start Courses)

Method	All dyads		Dyads w/o CSC		Only CSC dyads

LSTM-FM	0.603	0.437	0.603	0.436	0.606	0.476

FM and LSTM-FM with all features and FM and LSTM-FM with only selected features (Section 5.3).

We include several baseline methods for comparison: **uniform random (UR)** that randomly predicts a grade score from interval $[0, 4.3]$, **global mean (GM)** that predicts a grade score using the average of all observed grades in the training set, **mean of means (MoM)** that returns the average of (a) the predicted grade score of GM; (b) the average observed grades of this student in the training set; and (c) the average observed grades of this course in the training set, and **linear regression (LR)** that uses the first two components of FM ($w_0 + \sum_{k=1}^p w_k X_{i,j,k}$) to predict a grade.

5.3 Prediction Results

The overall prediction results are summarized in Table 3. UR yields the highest error. With the use of historical data, GM can predict with smaller errors. MoM further reduces the prediction error with more information used. By implementing a traditional machine learning approach, LR, we can obtain lower prediction error. The results show that the historical data contribute to grade prediction accuracy, and it is worthwhile to explore more machine learning approaches to improve this grade prediction task.

We then analyse the results of our proposed methods. It is interesting to see that FM with only student id and course id predicts grades quite well. It is also applied to LSTM-FM although the latter has a larger error. FM (and LSTM-FM) with all features actually performs worse than the one without features. With selected features (by excluding *cohort*, *disc_distrib*, *iid*, *term_dgrade*, and *lterm_cum_dgrade*), both methods achieve the best results. The overall results show that the lowest error obtained by LR in every scenario is always higher than those of FM and LSTM-FM. This suggests that the 2-way interaction captured in both FM and LSTM-FM can improve prediction accuracy compared to LR that only captures linear model. The results so far are encouraging as an MAE of 0.425 is smaller than a $\frac{3}{4}$ grade difference. We evaluate the methods for dyads that do not involve CSC to see if they are able to improve prediction accuracy. Table 3 shows that CSC dyads do not make significant difference to the prediction results. This suggests that the methods are robust against CSC.

The prediction errors for each program term are illustrated in Figure 3. We observe that both FM and LSTM-FM have similar performance on predicting grades in every program

Figure 3: Prediction error per program term

term. The first two program terms t_1 and t_2 have relatively higher errors compared to the latter terms due to lesser training data. t_1 also handles grade prediction for cold start students. As the amount of training data increases, we notice a significant error improvement from term t_3 onwards. The error converges at term t_5 when the model has sufficient training data. For terms t_5 to t_8 , both methods can maintain the MAE to be below 0.401.

6. DISCUSSION AND FUTURE WORK

Based on the proposed framework in this paper, we plan to develop a grade prediction API for the university that can be used by both students and instructors. This may help students to select courses that are appropriate to enroll, given their performance in past terms. Instructors then may use this API to understand the class profile, see the predicted performance of their students and use this information to adjust class outline and delivery method. We plan to explore using course description and knowledge graph to improve prediction accuracy. More advanced deep learning models can also be introduced to explain the prediction results.

ABSTRACT

Effective peer assessment requires students to be attentive to the deficiencies in the work they rate. Thus, their reviews should identify problems. But what ways are there to check that they do? We attempt to automate the process of deciding whether a review comment detects a problem. We use over 18,000 review comments that were labeled by the reviewees as either detecting or not detecting a problem with the work. We deploy several traditional machine-learning models, as well as neural-network models using GloVe and BERT embeddings. We find that the best performer is the Hierarchical Attention Network classifier, followed by the Bidirectional Gated Recurrent Units (GRU) Attention and Capsule model with scores of %93.1 and %90.5 respectively. The best non-neural network model was the support vector machine with a score of 89.71%. This is followed by the Stochastic Gradient Descent model and the Logistic Regression model with 89.70% and 88.98%.

Peer assessment, problem detection, text mining, text analytics, machine learning

1. INTRODUCTION

Peer assessment—students giving feedback on each other’s work—has been a common educational practice for at least 50 years [1, 2] It provides students more copious and rapid feedback than an instructor would give, as well as reactions from a more authentic audience (the student’s peers). By concentrating on a limited number of works, peers can produce assessments with similar validity and reliability to those of instructors, whose time is spread more thinly over many students’ submissions [3]. Students who perform peer

assessment show a substantial increase in performance [4]. Moreover, studies uniformly report that students learn more by being reviewers than they learn from the reviews they receive [5, 6, 7, 8].

The need for peer assessment was felt more acutely after the rise of massive open online courses (MOOCs). With students paying little to no fees, MOOCs are not able to hire enough staff to assess all submitted work. Thus, MOOCs rely heavily on peer assessment [9, 10].

For students to gain from peer assessment, students must take the process seriously. They must think carefully and metacognitively about the works they are reviewing. To foster an atmosphere where students assess conscientiously, the instructor must train the students in reviewing—and follow up by assessing how well they perform this task [11]. But instructor assessment of students’ reviewing suffers from the same shortcomings as instructor assessment of students’ submitted work: it consumes much instructor time, is likely to be rushed, and is mostly summative; that is it evaluates how well the students have done, but does not directly help them improve their reviewing. Thus, considerable research has looked at other methods for assessing review quality [12].

Fundamentally, the quality of a review is related to whether it identifies ways for the author to improve the work. Thus, the review should point out shortcomings or problems the reviewer perceives in the reviewed work. This paper describes several approaches to automatically identifying whether review *comments*, which are responses to individual rubric items, do point out (alleged) problems with the work.

2. RELATED WORK

Previous approaches to evaluating peer-assessment reviews include calibration [13, 10, 14], reputation systems [15, 16], “back-reviews” (rejoinders) [17], natural language processing [18, 19, 20], logistic regression [21], and neural-network techniques [22]. Peer assessment has much in common with peer review, as used to vet scientific work for publication. Hua et al. [23] used NLP to automatically detect arguments in these reviews. Negi [24] used several AI techniques to detect suggestions in product reviews. Space does not permit

Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 704 - 709

elaboration of these methods, but a fuller discussion can be found in [our extended paper](#).

3. EXPERIMENTAL METHODOLOGIES

3.1 Data

The data used for our experiments comes from Expertiza [25], a peer-assessment platform for reviewing work developed by collaborative teams. For each review, the reviewer fills out a rubric, which consists of several criteria. Sample rubric items are, "How well does the code follow good Ruby and Rails coding practices?" "Is the user interface intuitive and easy to use?" Most criteria ask for a numeric rating as well as textual feedback. It is the textual feedback that we analyze in this work.

Our study is based on reviews of coding and documentation assignments from NCSU CSC 517, Object-Oriented Design and Development. To obtain labeled data for our research, we offered students a small amount of extra credit for tagging review comments they received, as either mentioning a problem or not. We spot-checked the student-assigned tags for the purpose of quality control. An example comment that does not mention a problem (tagged as 0) is, "The interface is easy to use and it is well described in the README file." One mentioning a problem (tagged as 1) is, "The implementation can only log one type of user on."

Several students had the opportunity to tag the same review comments. If multiple students tagged the same comment, inter-rater reliability (IRR) could be calculated. We used Krippendorff's α [26] as the metric for IRR. By dropping observations with conflicting tags, we have raised the Krippendorff's α associated with our dataset from 0.696 to 1.

The dataset was de-duplicated and balanced, resulting in a total of 18,354 observations. It was separated into training, validation, and testing sets in the ratio of 80:10:10. This split was used to find optimized hyperparameters with 5-fold cross-validation. Unless the dataset is large, the combination of observations used in the training and test sets can have an impact on how well the classifier performs. We compensated for this by using 20-fold cross-validation on our finalized classifiers with tuned hyperparameters and saving the resulting 20 scores for analysis.

3.2 Baseline Models

We set up our baseline using traditional machine-learning models, such as Support Vector Machine (SVM), SVM using Stochastic Gradient Descent (SGD), Multinomial Naïve Bayes (MNB), Logistic Regression (LR), Random Forest (RF), Gradient Boosting (GB), and AdaBoost (AB).

3.2.1 Input Embedding

The input to our baseline models was first processed by the TF-IDF vectorizer in scikit-learn [27]. TF-IDF vectorization is a common way to convert raw text and documents into embeddings suitable for machine-learning models. The vectorizer generates a document-vocabulary matrix for each of the documents (in our case, review comments that averaged 2.2 sentences per comment). Then, using inverse document frequency, it normalizes ("lowers") the weight of the words by checking how often a word appears in other documents

(comments, in this case). This helps lessen the impact of frequent yet unimportant words, so that common words like "the" that convey little semantic meaning do not affect the classification of a comment. The model architecture and dataflow for traditional classifiers is shown in Figure 1.

3.2.2 Support Vector Machine

Support vector machines are commonly used for classification in machine learning. A SVM establishes a decision boundary as well as a positive plane and a negative plane between classes. Statistical features for each review comment represented in TF-IDF-normalized vectors are put into the vector space for all comments, then the model learns a hyper-plane (support vector) to best divide them into two categories: comments containing problem statements, and comments without problem statements.

Figure 1: Data pipeline for machine learning model

3.2.3 SVM with Stochastic Gradient Descent

Stochastic Gradient Descent (SGD) was developed early on and popularly adopted to optimize neural-network models [28], while applying SGD on linear classifiers is not unheard of. [29] We compared the performance of the SVM model with and without SGD. We applied a combination of L1 and L2 regularization to the loss function, with the hope of correcting over-fitting problems.

3.2.4 Multinomial Naïve Bayes

A naïve Bayes model assumes that each of the features it uses for classification is independent the others. To determine whether a review comment identifies a problem, the model examines the TF-IDF normalized word-count vectors for that comment, using the conditional probability of each of these features/vectors, and makes a judgment, based on conditional probabilities learned from the training set.

3.2.5 Logistic Regression

The logistic-regression (LR) classifier uses a regression equation to produce discrete binary outputs. Similar to linear regression, it learns the coefficients of each input feature through training; however it uses a logistic function instead of linear activation to determine the class to which an input belongs by fitting coefficients of each n-gram through comments in the given training set.

3.2.6 Random Forest

The Random Forest (RF) classifier is an ensemble method that fits multiple decision trees and uses averaging to improve the accuracy of predictions and to avoid over-fitting.

3.2.7 Gradient Boosting

Gradient boosting (GB) is an ensemble machine-learning algorithm that utilizes a number of weak models, such as small

decision trees. In training, these small decision trees are fitted in a negative gradient direction in order to reduce the loss calculated from the cost function.

3.2.8 AdaBoost

AdaBoost, or adaptive boosting, is a meta-algorithm that alters weights of entries for base models. When an entry is misclassified, the algorithm increases the weight of that entry and decreases the weights of entries that have been correctly classified. The algorithm terminates upon meeting the confidence threshold. Through doing this, the booster identifies the features that have greater impact on the results, and improves prediction accuracy.

3.3 Neural Network Models

Our other experiments use neural networks, and Keras [30] was the framework of choice for implementation. Compared with our baseline models, the input of each model is generated in two different ways: through a GloVe embedding and BERT embedding.

3.3.1 Input Embedding

Global Vectors for Word Representation, or GloVe embedding [31], is an embedding model that converts words into multidimensional vectors based on their meaning. Its function is similar to Word2Vec, which transforms words to embeddings in a limited vector space, though the underlying principle is different.

Bidirectional Encoder Representations from Transformers (BERT) is a multi-layer bidirectional transformer encoder [32] developed by Google. The BERT network we used in our experiment is published by Google and is pre-trained on Wikipedia and BooksCorpus data. We used the open-source project "Bert-as-service" to create sentence embeddings. Specifically, we limited the maximum sentence length to 25 words, and extracted embeddings with outputs from the second-last layer in the pretrained network. The Bert-Base-Uncased model [32] has 12 attention layers, and 768 neurons in each layer with 12 attention heads. Using this network has given us 768 dimensions as sentence embeddings. We also used a version with word level embeddings. Figure 2 demonstrates the model architectures in order of the next subsection.

3.3.2 Multilayer Perceptron

A multilayer perceptron (MLP) model [33] is a typical artificial neural network. It utilizes multiple layers of neurons, and uses back-propagation for training. Errors calculated by a loss function are propagated back through the layers using the chain rule of gradient descent derivation.

3.3.3 Convolutional Neural Network

A convolutional neural network (CNN) utilizes convolution kernels that pool data with a defined window size on given dimensions to generate summaries from input data [34].

When dealing with comment classification, this model uses convolutions on the feature dimension to reduce the complexity of each word vector, different dropout percentages, and pooling methods.

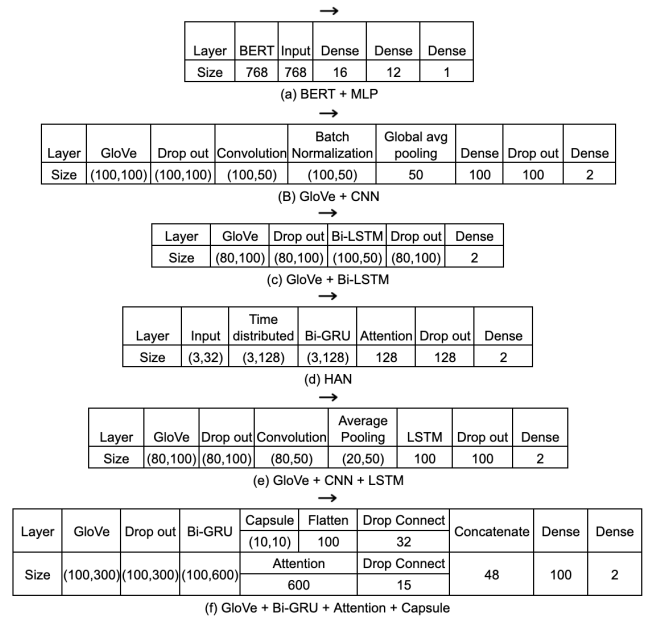

Figure 2: Data pipeline for neural network Models

3.3.4 Recurrent Neural Network

Recurrent neural networks (RNNs) are neural networks that take time-sequence information into consideration. For each time-step, the network takes the inputs and updates its internal memory cells with new information. Different RNN models implement memory updates differently. For example, long short-term memory (LSTM) networks not only remember inputs, but also "forget" unimportant information.

When we pass an embedded sentence to the network, each word is seen as an item emerging in one time step, and the sequence of words in a sentence becomes a sequence of vectors transitioning along with time steps. The neural network learns from the transition what information is important to keep and what is not, then applies the same judgment when a new sentence is given to it for classification.

Here we also implemented a GRU network and a bidirectional GRU network in parallel.

3.3.5 Hierarchical Attention Network

Hierarchical attention networks (HANs) are neural networks that take into consideration the document structure and sentence structure [35]. A document normally consists of a number of sentences, and a sentence is formed by a number of words. Not all sentences in a document are important to the classification of a document, and similarly, not all words are important for sentence-level classification. HANs utilize this information through attention layers that capture words and sentences that are important towards the classification.

In classifying comments, a HAN can capture information with greater impact on the results. For example in sample comment "The writeup does not include a Test Plan section," the words "does not include" contributes a lot more to implying there is a problem stated in this comment than other parts of the comment do.

3.3.6 CNN with Long Short Term Memory

Previous models showed that each type of the neural network or neural network layer could be efficient on specific tasks, for example CNN for dimension reduction and HAN for extracting words that are more important to the result. In this subsection we combine some models and explore the benefits of mixing different types of neural networks.

A model with CNN and LSTM layers is implemented in the hope of securing benefits from both models. With CNN as a dimension reducer, the LSTM layer might be able to find useful information from the aggregated features. Another attempt tests whether a CNN is needed to reduce dimensions, by removing it while boosting the performance of recurrent layer by putting it in a bidirectional wrapper.

4. EXPERIMENTAL RESULTS

Figure 3 displays a boxplot of the 20 f1-scores obtained using the traditional machine-learning classifiers and neural networks from the 20-fold cross validation. The lowest-performing classical machine learning classifiers, multinomial naïve Bayes and AdaBoost, achieved similar accuracy, with respective sample median f1-scores of 0.855 and 0.861. The gradient boosting and random-forest classifiers achieved sample median f1-scores of 0.870 and 0.871. The highest performing classifiers included logistic regression, stochastic gradient descent, and support vector machines. They achieved sample median f1-scores of 0.890, 0.897, and 0.897 respectively.

Figure 3: Models' F-1 Scores

These results show that classifiers can classify review comments as mentioning problems with an accuracy range of approximately 84% to 95%.

The HAN and BiGRU-Attn-Caps models that used GloVe embeddings achieved the best performance among all the models. The CNN model that used GloVe embeddings achieved the next best performance with a sample median f1-score of 0.886. The Bidirectional GRU had a very close sample median f1-score of 0.882, followed by the Bidirectional LSTM model with 0.872, then the LSTM CNN model at 0.865. The lowest-scoring models were the ones with word-level (WL-

Bert) and sentence-level (SL-Bert) BERT embeddings with sample median f1-scores of 0.862 and 0.844 respectively.

To gain insight into the phrases that contributed towards determining a suggestion, we extract coefficient weights of some features from two of the models. Table 1 displays a list of the logistic regression model's top 10 positive and negative features in determining if a comment has mentioned a problem in the author's work. The features that increase the likelihood that a comment will mention a problem (positive coefficients) include phrases that may constitute a suggestion by the reviewer. For instance, phrases such as "could", "should", "could have", and "more" indicate that the reviewer is likely giving advice to the author about improving the work, thus noting a problem by implication. Features with negative coefficients include phrases that likely demonstrate positive sentiment, such as "yes", "good", "well", and "great".

Table 1: Logistic Regression Coefficients

Coefficient	Value	Coefficient	Value

5. SUMMARY

We have marshalled a multitude of classifiers that can parse student peer-review comments for the detecting the mention of a problem. The HAN and BiGRU-Attn-Caps models performed the best among the neural network classifiers on this dataset, while the best traditional classifiers were the support vector machine and stochastic gradient descent models. The least effective classical models were the AdaBoost and multinomial naïve Bayes classifiers—the two that used the sentence and word level embeddings.

ABSTRACT

Time series data that exhibit skewed distribution is a common and important issue related to advanced model adoption, which however may be mis-specified when the data become extremely large and completely stochastic. This study adopted an experience-to-model approach in order to address the data skewness problem in educational data mining and in parallel explain the practical pedagogical meaning of data distribution patterns. To do this, we first specified a proper analysis granularity with respect to temporal data and provided evidence of its non-normality, and finally handled the skewness by correlating it to gaussian mixture models. We performed a scalable model by adaptively selecting the parameters and discussed the similarity measure based on probability density distribution.

Keywords

Data skewness, temporal pattern, data transformation, e-learning

1. INTRODUCTION

In recent years, big data in education is becoming a new driving force and playing an increasingly important role in educational research and practice[1]. The mining of big data in education is beneficial for educators and organizations to understand the learning patterns of students, optimize curriculum design, gain insight into student characteristics, provide high-quality educational decisions, and finally improve students' academic standards[2-4].

One of main challenges, however, is that the data is not always of normal distribution, which makes many standard approaches limited and corresponding results not robust. Many studies either ignored the existence of this challenge or simplified the assumptions of research conditions. Pearson correlation, for example, is used for testing linear dependence between a couple of variables assuming the data is small and has a normal shape. But the model can be easily mis-specified because the feasibility of this assumption is weakened when the data become extremely large and completely stochastic. Besides, many scholars use machine learning algorithms to classify the time series data without paying much attentions to the data distributions, leading to seriously inaccurate results due to the fact that the performances of classifiers

are subject to the data presented to it during training session and many attributes of the data are not balanced[5]. The imbalanced data distribution is usually described by a skewness coefficient in statistics representing an asymmetry from the mean of a data distribution. Time series data that exhibit skewed behavior is a common and important issue related to advanced model adoption of educational data mining[6].

This study adopts an experience-to-model approach in order to address the data skewness problem in educational data mining and in parallel explain the practical meaning of data distribution patterns. To do this, we first summarized coarse-grained observations on temporal data that collected from online courses, and then discussed the non-normality of time series data in education based on carefully selected granularity. Finally, we provided a tutorial to handle the skewness by correlating it to gaussian mixture models.

2. RELATED WORK

Temporal data has been studied in many research domains, while there is only a little literature has been documented in the educational domain. The current research on educational temporal data has mainly focused on online courses and metacognition. For example, authors in[7] proposed a temporal modeling approach for students' dropout prediction in MOOCs, authors in[8] mined temporal characteristics of learning behaviors from e-learning systems, and authors in[9] obtained sequential and temporal characteristics of self and socially regulated learning. Many of these research omitted the distribution assumption of data samples, which may lead to improper explanations related to statistical values. As is known, the Gaussian distribution is well known and widely applied by assuming that the aggregate effect of many individual independent components tends to be distributed with symmetrical bell curve. However, the use of Gaussian-based statistics can result in substantial error if problems are involved a lot of skewed data[10]. The assumption of homogeneity of variance indicates that the variance of the variable remains constant over the observed range, which may not be the truth in most research scenarios. Although the current statistical software packages provide tools to test the normality assumptions, and a lot of literature have documented to use multiple regression model and ANOVA model for modest violations to these assumptions[11]. A more effective way, however, is to transform data to improve normality of independent variables when substantial non-normality is present. Data transformations can improve normality of a distribution and equalizing variance in quantitative analysis of data. For this reason, this study will conduct experiments based on this approach. In previous works, the transformation approaches include adding constants, square root transformation, log transformation, scales, inverse transformation, arcsine

Tao Xie, Chaohua Gong and Geping Liu "An Empirical Analysis of Skewed Temporal Data for Distribution-based Course Similarity" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 710 - 714

transformation and Box-Cox transformation[12]. Many of these approaches are showing good properties of distribution symmetry.

Besides, the data skewness problem has been extensively studied in communities of time series mining. It is claimed that the skewness has significantly influence on the performance of algorithmic tasks[13], where the authors have to detect the degree of skewness to determine the characteristics of the dataset distribution. To explore such influences, the relationship between data skewness and accuracy of data mining models has been examined in[14] and[15]. Because the irregular sampling of data sets is often encountered in time series, the measures of skewness are also of great interest and have become especially important while conducting data cleaning and data preprocessing. Therefore, authors in[16] devised an approach to transform the time series segments to produce new ones so that the new ones can be analyzed using standard methods, which is in essence consistent with data transformation techniques as stated above. This study uses quadratic square root approach on temporal data and compares the difference in the developed metrics between original and transformed data on online courses.

3. DATA

3.1 Data Collection

There are 14 million video-viewing logs collected from 57,717 students. We choose the top 7 video courses with the most in-course interactions, which are respectively Introduction to Mao Thought (MS), Political Economy (PE), Linear Algebra (LA), Enterprise Financial Management (EF), Marketing (MM), Microcomputer Principle and Interface (MI), and Health Assessment (HA). Finally, we keep information of 7,341 students. One-way ANOVA shows that the differences between groups in terms of the continuous variables are statistically significant at the 0.05 level ($df = 6, p = 0.00$) and the differences between groups in terms of the age and video-viewing time have statistical significance at the 0.05 level ($df = 4, p = 0.00$).

3.2 Granularity of Analysis

In information systems, time is mainly represented by time points and time intervals. Time describes the moment at which learning behaviors occur, while time interval describes the length during which the behaviors last. They are used to present a certain chronological order, cycle characteristics, and time association rules. Since the current analysis unit is the temporal data, time-related information of interest is abstracted. Each student has plenty of but usually intermittent interactions with systems. In order to summarize the statistic distributions, this study focuses on the total time during which a player is always in the playing state. The video-viewing time is an absolute measure representing the length of content students learn, while we also consider a relative measure called the viewing completion ratio, which is the proportion of video-viewing time with respect to the total video length and represents the progress of content consumption.

3.3 Preliminary observations

The most active period for students watching videos is from the November of the second half of the year to the early January of the following year. The effective learning days of the week are workdays, and ineffective learning days are weekends. The study period of the day is mainly from 9 am to 6 pm. During mealtime and other breaks such as the evenings, students rarely watch videos. Students who use mobile devices have different temporal patterns.

For each course, the cumulative playing time of most students is less than 1 minute. This shows that this part of students is not advanced students[17]. Their behavioral pattern can be attributed to “zapping style” according to[18]. There are also some students whose cumulative playing time exceeds the total length of the video and the corresponding learning completion rate is greater than 1, which indicates that these students have played the complete video from the beginning to the end or watched specific segments of the video repeatedly. In other words, their watching pattern can be attributed to repetitive style[18].

As the length of time increases, the probability density first decreases rapidly to a specific value, then reaches a peak at a faster rate and produce a thick tail. For each course, the peak of the probability density curve is relatively close in time and has a similar co-increasing or co-decreasing trend. This shows that the students' learning of the courses shares a similar distribution pattern.

The average of viewing time and the viewing completion rate are both close and low. The average cumulative viewing time for each course is about 13 minutes, and the average completion rate of video viewing is about 40%. These two values reflect the phenomena reported by most MOOC studies: high dropout rates and low resource utilization. It also shows that, compared to non-educational videos, educational videos have specific non-linear viewing patterns and a clear cognitive search intent[19].

4. RESULTS

4.1 Skewness

We perform a Kolmogorov-Smirnov normality test on the selected 7 courses. The established null hypothesis is that the viewing time or viewing completion rate conforms to a distribution of a specific normal shape. At 95% confidence and 0.05 significance level, we calculated two-tailed p-values for the two indicators which are showing equivalence to 0.000. In addition, we calculate the D statistic, which tells the maximum distance of the cumulative distribution function between the data distribution and the fitted normal distribution. More intuitively, it quantifies the magnitude of the difference between two distributions. For each course sample, the D value is large.

Besides, we observed the kurtosis and skewness coefficients. We can find that the probability density curve has a sharp peak and right-skewed shape. The right skewed distribution has a property that the mean value in the horizontal direction is greater than the median and mode[20], and the absolute value of most skewness is greater than 1.96 times its standard error, which indicates that the skewed distribution and the symmetrical distribution have statistics significance. Like the average viewing time, the distribution of viewing completion rates is all right-biased except MM, and the relationship between the median and the mean satisfies the corresponding skewed properties.

Because of data skewness, it is not appropriate to use standard methods that are based on normal distribution assumption. There are generally two methods for processing skewed data. The first method based on fitting a series of models has been implemented in[21], and the current study will try the second approach to obtain more rich features through data transformation.

4.2 Data Transformation

Intuitively, the right-biased distribution of the data causes the probability density of the long tail to change relatively slowly. This means that once students exceed the average viewing time threshold, they will have a higher proportion to invest more time in

courses. Conversely, if students' learning time does not reach this threshold, they will have a higher percentage of withdrawal from the course. Indeed, it is observable that many students fall into the second category. In order to make the curve more symmetrical, we compress the spacing of the data. This requires that the spacing of the long-tail portion is compressed faster, while the short-tail portion is compressed more slowly. After trying a lot of models empirically, we found that quadratic square root of the original data can make the data distribution basically symmetrical, and its effect is better than other available methods, such as natural logarithm. We further use the local quadratic regression on the transformed data to smooth the data. Let the range of the temporal variable X be D . For each sample $x_0 \in D$, we choose a neighborhood of x_0 . Fit the dependent variable corresponding to the observations of the temporal variables that fall within this neighborhood using the weighted least squares method. The value of the curve at x_0 is an estimate of the regression function. The results are showing in Figure 1.

Figure 1. Curve smoothing with respect to video viewing time

The transformed time series does not satisfy any single type of distribution but presents the characteristics of a multimodal distribution. In addition to the main peak in the middle of the curve, at least one small peak may appear near the beginning or the end of the curve. In order to evaluate the goodness of fit, we use maximum likelihood estimation to fit the set of curves. Note that the current curve has a more pronounced symmetrical property near each peak than the original curve, which inspired us to try a gaussian mixture model. Suppose a curve approximates a k , $k \geq 2$ normal mixed distribution, the probability density of the curve can be expressed as:

$$p(x) = \sum_{i=1}^k \lambda_i p_i(x), \quad (1)$$

where λ_i is the weight of the i 'th gaussian distribution, satisfying $\sum_{i=1}^k \lambda_i = 1$, and $p_i(x)$ is probability density function of the i 'th gaussian distribution, satisfying $p_i(x) \sim (u_i, \sigma_i^2)$. To prevent overfitting due to empirical selection, we consider only the simplest $k = 2$ here, and compare its goodness of fit with a single normal distribution to choose the right fitting model.

Evaluation metrics include root mean square error (RMSE), adjusted R^2 , and Akaike's Information Criterion (AIC). They are showing in Table 1 that for all courses the binormal distribution is better than the single normal distribution. Numerically, it always has $RMSE_{k=2} < RMSE_{k=1}$, $R^2_{k=2} > R^2_{k=1}$, and $AIC_{k=2} < AIC_{k=1}$. We can also find that in the two models, the biggest improvement is LA, which means that its binormal distribution feature is more significant. While for MS with little improvement, both single and binormal distributions can be used for fitting. This may depend on the course setting. MS is a campus-wide elective course, which has

large number of samples and thus shows more characteristics of normal distribution according to the central limit theorem[22]. Additionally, EF, MI, and HA courses have smaller AIC values, indicating that they are suitable for a binormal distribution. In order to quantitatively evaluate the improved effect size, we focus on the AIC indicator considering that it imposes more stringent penalties on the complexity of the model compared to other indicators, so that the model we choose not only has the minimum parameters but also prevents overfitting[23, 24]. The effect size can be calculated as the improvement ratio of the AIC value while using the binormal distribution versus the single normal distribution. Results show that the most improved course when using binormal distribution fitting is HA, followed by MI, and the least improvement is MS.

The statistical characteristics of the bimodal distribution indicate that there are different dropout and retention patterns for students in all courses; courses with greater differences in the goodness of fit between single and binormal distributions, say LA and MM, show higher retention rates; instead, courses with smaller differences in goodness of fit between single and binormal

distributions such as MS show a more prominent dropout pattern, which should be given sufficient attentions by course organizers and educators.

Table 1. Evaluation of distributions.

	Single normal distribution			Binormal distribution		
	RMSE	Adj. R^2	AIC	RMSE	Adj. R^2	AIC
MS	2.297	0.912	223.8	2.236	0.917	172.9
PE	2.973	0.890	223.9	1.629	0.967	109.6
LA	4.948	0.652	325.8	1.705	0.959	118.7
EF	2.142	0.922	158.3	1.097	0.980	30.5
MM	5.461	0.780	345.6	2.233	0.963	172.7
MI	2.542	0.916	192.6	1.029	0.986	17.7
HA	2.775	0.917	208.7	0.92	0.991	-4.6

Repeating the above experimental process, we find that the distribution of the viewing completion rate is more complicated than that of the viewing time. If we use k mixed distribution for fitting, usually the goodness of fitting can be obtained when $k > 3$. Since the discussion of $k > 3$ is too complicated, we will deal with it by generalizing the model for arbitrary k values in Section 5. In order to reflect more details of the student learning process, we borrow the concept of temporal structure. We argue that it reflects the change of students' time investment when watching the courses, which is helpful for further analysis of students' preferences for in-

course parts. It should be noted that viewing time is different from time investment. The former is a static quantity that measures how much time is invested, and the latter is a dynamic quantity that measures the difference in structure of time investment.

4.3 Variation of Temporal Structure

In order to quantitatively describe the difference in the temporal structure of the viewing sequences, we use the coefficient of variation termed CV, which can be calculated by dividing the standard deviation by the mean.

$$CV = \sigma_x / \bar{x}, \quad (2)$$

where σ_x is the standard deviation and \bar{x} is the mean. The results are shown in the third column of Table 2. The numbers outside the brackets indicate the coefficient of variation of the original data, and the numbers inside the brackets indicate the transformed coefficient of variation.

Given that the amount of student watching is positively proportional to the time the student spends on the courses, we can evaluate the temporal structure of the video viewing sequence to reflect the rationality of the time allocation when students watches the courses. In this regard, Gini coefficient is a suitable indicator, which is shown in columns 6 and 7. It can be learned that the Gini coefficient with respect to viewing time (G-VT) and the Gini coefficient with respect to viewing completion rate (G-VCR) in the same course are relatively close. The two courses with the largest Gini coefficients are EF and MI, and the smallest are LA in G-VT and MM in G-VCR. This result shows that the time structure of the student's consumption ratio of EF and MI is slightly less reasonable than other courses.

Table 2. Measures of temporal structure

	CV	G-VT	G-VCR	ρ
MS	0.744(0.428)	0.399(0.234)	0.392(0.228)	0.999
PE	0.709(0.323)	0.391(0.237)	0.398(0.239)	1.000
LA	0.688(0.400)	0.377(0.223)	0.392(0.234)	1.000
EF	0.770(0.451)	0.410(0.252)	0.405(0.253)	0.990
MM	0.750(0.433)	0.400(0.244)	0.369(0.232)	0.993
MI	0.772(0.441)	0.412(0.246)	0.406(0.234)	0.992
HA	0.780(0.423)	0.397(0.234)	0.388(0.224)	0.948

It is worth noting that CV and Gini characterize the difference in the temporal structure with respect to viewing time and the completion rate of learning, but they show amazing consistency in values. According to literature[25], The Gini coefficient can be approximated as:

$$G = \frac{1}{\sqrt{3}} \frac{\sigma_y}{\bar{y}} \rho(y, r), \quad (3)$$

where σ_y represents the standard deviation, \bar{y} represents the mean, and $\rho(y, r)$ is the correlation coefficient between the student's cumulative viewing and his rank in the population. Both

the CV and Gini calculation formulas have the same component, i.e. standard deviation and mean. There is a strong positive correlation between the CV of the transformed data and the G-VT of the original data obtained by the spearman rank correlation test at a significance level of 0.01(coef. = 0.929, p = 0.003); and there is a positive correlation between the CV of the transformed data and the transformed G-VT at a significance level of 0.05(coef. = 0.683, p = 0.033). Bringing the mean and standard deviation of Table 2 into the formula, we obtain the ρ values.

5. Course Similarity

5.1 Metric

In order to make the model scalable, we assume that other courses can also be fitted with the gaussian mixture model by choosing the appropriate k value.

For each course, we run GMM clustering algorithm and obtain parameters of GMM. The log-likelihood function can be written as:

$$l(\pi, \mu, \sigma) = \sum_{i=1}^N \log \left(\sum_{k=1}^K \pi_k P(x_i; \mu_k, \sigma_k) \right). \quad (4)$$

K-means algorithm is used to initialize model parameters and EM algorithm is used to optimize the parameters.

Given two course samples C^i and C^j , we model them as gaussian mixture model $\Omega^i = \{\phi_1^i, \phi_2^i, \dots, \phi_{K_1}^i\}$ and $\Omega^j = \{\phi_1^j, \phi_2^j, \dots, \phi_{K_2}^j\}$

where K_1 and K_2 are the number of components of Ω^i and Ω^j respectively. Then, the average similarity of the two course distributions[26] can be computed by:

$$S(\Omega^i, \Omega^j) = 1 - \frac{1}{K_1 K_2} \sum_{h=1}^{K_1} \sum_{l=1}^{K_2} d(\phi_h^i, \phi_l^j), \quad (5)$$

$$d(\phi_m^i, \phi_n^j) = \frac{1}{8} (\mu_m^i - \mu_n^j)^T \left(\frac{\Sigma_m^i + \Sigma_n^j}{2} \right)^{-1} (\mu_m^i - \mu_n^j) + \frac{1}{2} \ln \frac{\left| \frac{\Sigma_m^i + \Sigma_n^j}{2} \right|}{\sqrt{|\Sigma_m^i| |\Sigma_n^j|}}, \quad (6)$$

where $d(\phi_m^i, \phi_n^j)$ is the Bhattacharyya distance that measures the pair-wise similarity of multivariate normal distributions. The bigger of the S value, the similar of the course samples.

5.2 Discussion

The distribution-based course similarity can be applied to personalized course recommendation that addresses the information overload issue by customizing the learning content for students[27]. In previous studies, teachers describe the attributes of courses by analyzing their content, or pre-define corresponding learning goals as the extent to which students would acquire knowledge and skills[28]. The obvious limitation is the lack of a dynamic description of the learning process. Existing course similarity calculation are mainly based on the traditional text mining approaches with a vector space model been constructed according to the knowledge points that each course contains[29]. They mainly suffer from not considering the real-time temporal access patterns towards courses. The courses in the same cluster summarize students' similar learning patterns, which is helpful for assessing the learning process of students.

ABSTRACT

In data collected from virtual learning environments (VLEs), item response theory (IRT) models can be used to guide the ongoing measurement of student ability. However, such applications of IRT rely on unbiased item parameter estimates associated with test items in the VLE. Without formal piloting of the items, one can expect a large amount of non-ignorable missing data in the VLE log file data, and this is expected to negatively impact IRT item parameter estimation accuracy, which then negatively impacts any future ability estimates utilized in the VLE. In the psychometric literature, methods for handling missing data are mostly centered around conditions in which the data and the amount of missing data are not as large as those that come from VLEs. In this paper, we introduce a semi-supervised learning method to deal with a large proportion of missingness contained in VLE data from which one needs to obtain unbiased item parameter estimates. The proposed framework showed its potential for obtaining unbiased item parameter estimates that can then be fixed in the VLE in order to obtain ongoing ability estimates for operational purposes.

Keywords

virtual learning environment, semi-supervised learning, item response theory, missing data

1. INTRODUCTION

In contrast to physical learning environments such as classrooms, a virtual learning environment (VLE) refers to a system that delivers learning materials to students in a digital space. Item response theory (IRT) [3] refers to a family

of mathematical models that attempt to explain the relationship between latent traits (unobservable skills or knowledge) and their manifestations (i.e. observed outcomes, responses or performance) using different statistic functions (e.g. Rasch Model, 2PL-IRT, multidimensional IRT). To estimate the item parameters for further personal adaptive learning (e.g., providing appropriate item which matches student's ability could encourage student to complete it), IRT models are widely used to determine the psychometric properties of items through analyzing students' responses in VLE [9].

How to reduce the impact of missing values on item parameter estimation of IRT models is a very common issue for data analysis and attracts lots of research attention. Generally, missing values could be categorized to 4 classes: structurally missing data, missing completely at random (MCAR), missing at random (MAR) and missing not at random (i.e. non-ignorable missing values) [12]. In contrast to other types of missing values, nonignorable missing values in assessment are more complicated because they are usually caused by latent factors to be measured by IRT models. For assessment data, researchers has proposed different model-based approaches to reduce the impacts from nonignorable missing values [10]. One model-based approach, the latent approach, includes missing tendency via a latent missing propensity that is accounted for in a multidimensional IRT model [4]; another model-based approach, the manifest approach, includes missing tendency by modeling a manifest missing variable that is accounted for in a unidimensional missingness propensity [11].

However, in contrast to assessment, the data collected in VLE often contain large proportion of missingness when students are allowed to skip questions in some online courses. It makes that the missing data in VLEs are caused by a variety of cognitive and motivational factors (e.g., excess challenge, lack of challenge or lack of time). The model-based approaches are not suitable to deal with such kinds of missingness in the data collected from VLE, because determining the latent missing propensity will be very complicated for drawing inferences to model the joint distribution of the missingness and the item responses [6].

The technological changes across learning, instruction and assessment start to bring machine learning techniques into psychometrics because machine learning algorithms have the

capability to analyzing complex and high-dimensional data. Applying data mining and machine learning techniques to VLE data is a mechanism to improve research in technology-enhanced educational environments [1, 8]. For example, IRT psychometric models are usually based upon logistic regression techniques which are used to be popular in solving classification problem in machine learning [7]. As a sub-field of machine learning, the primary goal of deep learning is to extract the latent variables from the input distribution using artificial neural networks (ANNs) which is a computational system inspired by biological neural networks [5]. In educational research area, deep learning has been applied for different tasks, such as automatic item generation (AIG) [14], automated scoring [13], and item characteristics prediction [17].

Inspired by the research using deep learning and semi-supervised learning techniques for cognitive diagnostic classification [15], we proposed a semi-supervised deep learning framework to reduce the impact on item parameter estimation caused by nonignorable missing values when applying two-parameter IRT (2PL-IRT) model to the data collected in VLE. The research in this paper consists of two parts: (1) exploring the real data collected within a statewide-used VLE to test if the missingness was caused by student ability and item difficulty which were measured in 2PL-IRT; and (2) proposing a semi-supervised learning method using deep learning techniques to adjust the bias in estimation caused by missingness. In the following part of this paper, we will firstly introduce the operational data exploration on the data collected within a VLE; then the semi-supervised learning method will be described in detail; the simulated study shows the performance of the proposed framework in dealing with nonignorable missingness; lastly, we will conclude the findings and limits in this framework and discuss some potential future research.

2. OPERATIONAL DATA EXPLORATION

The data collected in this research were students' responses to the "Algebra I" items within a statewide-used VLE system. The dataset contains 10 algebra domains, and we treated each domain as having its own ability to measure. The number of items ranged from 41 to 89 across domains. The total number of students was 63,625. Since students were allowed to skip items in the learning environment when they responded to the items which were selected by the system randomly, the responses to each item contained large amount of missing values. The proportion of missingness for each item is between 55% to 75%. Generally, the response patterns of students could be classified into 3 categories: 1) skipped the domain (i.e., no responses to any test items within the domain), 2) completed the domain (i.e., responded to all test items within the domain), 3) mixed response (i.e., responded to some items within the domain).

To test if the missingness was related to the item and person parameters in the 2PL-IRT model, a hierarchical logistic regression (Figure 1) was conducted for each domain individually. The hierarchical logistic regression was consisted of (1) **skipping domain test** was to test if skipping a domain related to the students' ability; (2) **completing domain test** was to test if completing a domain related to the students' ability; (3) **mixed response test** was to test if student

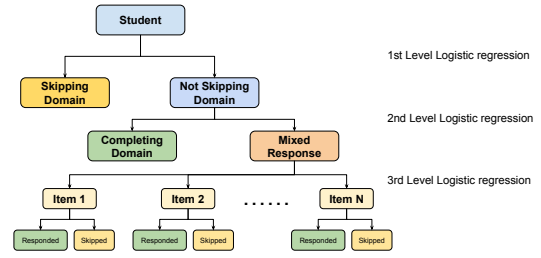

Figure 1: The diagram of the hierarchical logistic regression.

skipping an item related to the item difficulty and students ability. As an area of mathematics, there is high correlation between the math skills and algebra skills. Thus, we used the pretest mathematical scores on the state standardized test, S , as student's true ability for the data exploration. To evaluate the relationship between ability and skipping a domain, all the students' responses were classified to two groups: students skipped the domain and students didn't skip the domain. The second group contained students completed the domain and students with mixed responses. Then the logistic regression test was conducted for each school district individually as following:

$$\text{logit}(\text{skipping domain}) = \beta_{0,ij} + \beta_{1,ij}S \quad (1)$$

where j indicates the j th educational district and i refers to the i th domain. After fitting the models, we found that for most school districts and most students, $\beta_{1,ij}$ were significant negative. We can conclude that students with high ability level had a lower probability to skip a domain, and students with low ability level had higher probability to skip a domain.

After doing skipping domain test, in the completing domain test, the dataset only contained students who didn't skip the domain. The dataset was divided to two groups: students completed domain and students with mixed response. The logistic regression test was conducted for each school district individually as following:

$$\text{logit}(\text{completing domain}) = \beta_{0,ij} + \beta_{1,ij}S \quad (2)$$

where j indicates the j th educational district and i refers to the i th domain. In contrast to the observation of "skipping domain", it was not reasonable to reach a consistent conclusion about the relationship between the ability and completing domain.

In the last subtest, two factors, students' ability and item difficulty, were assumed to impact the probability that a student responded to an item. We chose the observed incorrect response rate of the item, D_k , to indicate the item difficulty. The logistic regression was as following:

$$\text{logit}(\text{skipping } k\text{th item}) = \beta_{0,ik} + \beta_{1,ik}S + \beta_{2,ik}D_k \quad (3)$$

where i is the i th domain and k indicates the k th item. The logistic regression test showed that students with lower ability level had higher probability to skip an item shown to them; and student had a higher probability to skip item with higher difficulties. From the data exploration, we could conclude that the missing values in the data collected contained

nonignorable missingness because they were caused the factors have relationship with the latent variables measured in the 2PL-IRT model.

3. SEMI-SUPERVISED DEEP LEARNING-BASED BIAS ADJUSTMENT

Intuitively, there was no missing value in the response from the anchor students, who completed all items in a domain. However, directly applying 2PL-IRT model to the anchor students would impact a parameter invariance because from the data exploration also showed there existed difference between the sub-population of anchor students and whole population. To adjust the biased ability estimates and item parameters estimates through directly applying 2PL-IRT model to the anchor students, we proposed a semi-supervised deep learning-based bias adjustment procedure which consisted of the unbiased ability estimation through a semi-supervised deep learning architecture, and the item parameter adjustment methods.

3.1 Semi-supervised deep learning architecture

The thinking of semi-supervised learning was used to improve the robustness of binary latent person variables (e.g. attribute mastery status) estimation [15]. In this research, because the latent person variables measured in 2PL-IRT model were continuous, the semi-supervised learning techniques were conducted based on the following two assumptions:

1. Given the unbiased latent trait Θ for each student, the biased estimation $\hat{\theta}$ directly using 2PL-IRT could be represented through a function: $\hat{\theta} = \phi(\Theta)$;
2. The unbiased latent trait Θ could maximize the likelihood function $P(X = 1; \Theta) = L(\Theta)$ which indicates the relationship between latent trait Θ and item response pattern $\mathbf{X} = \{x\}$;

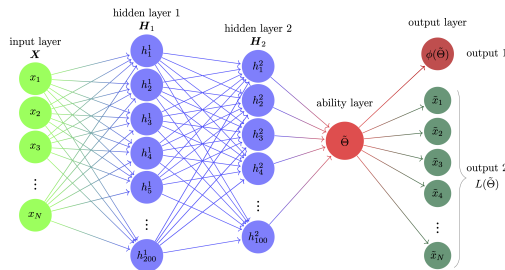

Figure 2: The diagram of the proposed semi-supervised deep learning architecture for unbiased ability estimation. In this framework, a deep learning architecture with 3 hidden layers was used to convert the observed response patterns to the unbiased ability. To train the deep learning architecture, the distance between two outputs of the DFN and two targets was minimized.

Regarding to these assumptions, the goals of the proposed semi-supervised deep learning structure to extract the unbiased latent trait Θ from the anchor students response data and approximate the function $\phi(\Theta)$ which indicated the relationship between unbiased latent trait Θ and biased estimation $\hat{\theta}$ and $L(\Theta)$ which indicates the relationship between

latent trait Θ and item response pattern $\mathbf{X} = \{x\}$. From Figure 2, there were three hidden layers between the input layer and the latent trait layer. The number of hidden layers were set based on the previous research of using deep learning method for cognitive diagnostic models [16, 2]. To bring the nonlinearity to the DFN, Rectified Linear Units (ReLU) was chosen as the activation function. The unbiased latent trait $\hat{\Theta}$ extracted using the DFN could be represented as: $\hat{\Theta} = \Phi(\mathbf{X}; \omega)$. ω were the connection weights in the DFN. The parameters of DFN, ω , were estimated by minimizing the following weighted cost function:

$$\omega = \arg \min(w_1 MSE(\hat{\theta}, \phi(\hat{\Theta})) + w_2 H(\hat{\mathbf{X}}, \mathbf{X})) \quad (4)$$

where $\hat{\theta}$ is the biased students' ability estimation directly fitting 2PL-IRT model to the anchor students' responses; $\mathbf{X} = \{x\}$ is the observed response patterns of the anchor students. In the weighted cost function, we used two kinds of error functions corresponding to two outputs respectively: the mean square error (MSE) was used to calculate the difference between continuous variables $\hat{\theta}$ and $\phi(\hat{\Theta})$; the cross-entropy (H) was used to calculate the difference between binary variables \mathbf{X} and $\hat{\mathbf{X}}$. The two hyperparameters, w_1 and w_2 , were determined using the elbow method in validation test.

3.2 Two item parameter adjustment methods

After obtaining the parameter estimation through the training procedure, the DFN converted observed response pattern \mathbf{X} to unbiased ability estimation $\hat{\Theta}$. To reduce the biases contained in the item difficulty, two kinds of adjustment methods, item equating adjustment (IEA) and bootstrapping adjustment (BA), were proposed using the unbiased ability estimation $\hat{\Theta}$.

IEA was inspired by the common group equating design in IRT. In IEA, the ability distribution of anchor students was the frame of reference. Then the biased item difficulty estimates were placed onto unbiased item difficulty via $\tilde{b}_j = \hat{b}_j - (\hat{\Theta} - \bar{\hat{\Theta}})$. $\bar{\hat{\theta}}$ and $\bar{\hat{\Theta}}$ are the average of biased ability estimates and unbiased ability estimates respectively, \hat{b}_j is the biased item difficulty estimates for j th item, and \tilde{b}_j is the adjusted item difficulty estimates. IEA only reduced the biases contained in the item difficulty estimates because it held an assumption that the item discrimination estimates were not biased.

In contrast to IEA, BA was proposed to reduce the biases contained in both item difficulty and item discrimination parameters using bootstrapping in statistics. There were 4 steps contained in BA method:

1. Randomly sampled from the anchor students based on the unbiased ability estimates $\hat{\Theta}$ to make the ability distribution of the new sample set is standard normal distribution and the sample size was same as the original anchor students;
2. Apply 2PL-IRT to the new sample set and estimate the item difficulty parameters and item discriminating parameters;
3. Repeated step 1 and step 2 K times, a group of estimates of difficulty and discriminating of j th item could be obtained $\{\tilde{a}_{j,k}, \tilde{b}_{j,k}\}$, where $k = 1, K$;

Table 1: Comparison of the distribution of ability estimates between directly 2PL-IRT model fitting ($\hat{\theta}$) and the proposed semi-supervised deep learning architecture ($\tilde{\theta}$).

Domains	True $\Theta(\sigma)$	$\hat{\theta}(\sigma)$	$\tilde{\theta}(\sigma)$
1	0.090 (0.93)	-0.001 (0.99)	0.095 (0.90)
2	0.169 (0.85)	0.000 (0.98)	0.157 (0.82)
3	0.203 (0.83)	0.000 (1.01)	0.198 (0.85)
4	0.152 (0.88)	-0.001 (0.99)	0.160 (0.81)
5	0.178 (0.87)	-0.001 (1.00)	0.180 (0.88)
6	0.228 (0.75)	-0.001 (0.99)	0.232 (0.73)
7	0.168 (0.85)	-0.001 (1.01)	0.171 (0.83)
8	0.218 (0.79)	-0.000 (1.00)	0.207 (0.80)
9	0.241 (0.77)	-0.000 (1.00)	0.241 (0.79)
9	0.312 (0.72)	-0.000 (0.98)	0.320 (0.69)

4. Then the estimate of item discrimination equaled to $\frac{1}{K} \sum_1^K \tilde{a}_{j,k}$, and the estimate of item difficulty equaled to $\frac{1}{K} \sum_1^K \tilde{b}_{j,k}$.

The BA method relies on less constraint and could reduce the biases contained in both item discrimination and difficulty estimates. The BA has the potential for applying on more complicated IRT models, such as 3PL-IRT.

4. SIMULATED STUDY

The proposed methods were tested through a simulation study under 2PL-IRT model. In the simulated study, we used “mirt” package in R to conduct data simulation and IRT model fitting and used “Tensorflow” toolbox in python to achieve the unbiased ability estimates through the semi-supervised deep learning architecture. To create data under 2PL-IRT, the known pretest mathematical ability were used as the students’ ability, and the biased item parameters obtained through directly applying 2PL-IRT to the anchor students were used as item parameters. The fitted functions 1, 2, and 3 in data exploration were used to predict the students’ response patterns (e.g., skipping domain, completing domain, mixed response). We selected the response of anchor students who completed all items in a domain as the input of our proposed method.

First, we applied the 2PL-IRT model directly to the simulated anchor students’ responses for each domain to estimate the item parameters and students’ ability. Then, the proposed semi-supervised deep learning architecture was applied using the simulated anchor students’ responses as input and using the anchor students’ ability estimates and their response patterns as two targets. By minimizing the weighted cost function in Equation 4, the unbiased ability of anchor students was estimated. The validating test was conducted in the training procedure to avoid over-fitting and determine the two hyperparameters w_1 and w_2 in Equation 4. Table 4 compares the distribution of ability estimates between directly 2PL-IRT model fitting and the proposed semi-supervised deep learning architecture.

Using the estimation of the anchor students’ ability through the semi-supervised deep learning architecture, the two proposed adjustment methods, IEA and BA, were conducted to reduce the biases contained in the item difficulty parameters. We chose two criteria, rooted mean squared er-

ror (RMSE) and variance, to evaluate the bias adjustment methods. RMSE indicates the distance between item difficulty estimates and true item difficulty parameters, and the variance indicates the consistency of the estimates from different methods. From Figure 3, in contrast to the directly 2PL-IRT model fitting, both IEA and BA achieved much less RMSE for each domain. For variance, since the IEA adjusted the difficulty estimates based on a parallel shift of the ability distribution, the variance of IEA and directly 2PL-IRT results were the same. However, the BA method obtained more consistent estimates because bootstrapping in BA created standard normal distributed samples which matched the assumption of original IRT estimation. From the experimental results, both IEA and BA had the ability to adjust the biases contained in the estimates of item difficulty using directly 2PL-IRT model fitting. Compared with IEA which only reduce the biases of item difficulty parameters, BA method had the potential to reduce the biases contained in the item parameters for different IRT models.

Figure 3: Comparison of the item difficulty estimates among direct applying 2PL-IRT model fitting, item equating adjustment (IEA) and bootstrapping adjustment (BA).

5. CONCLUSION

Nonignorable missingness impacts applying psychometric models to the data collected in VLE. To reduce the impacts of nonignorable missingness, this research explored a statewide-used VLE data to test the hypothesis that the missing values were non-ignorable missingness and related to the factors that 2PL-IRT model measures. The data exploration showed that the non-ignorable missingness would impact the parameter estimation of 2PL-IRT without pre data analysis. To adjust the biased item difficulty parameter estimates caused by the non-ignorable missingness, a semi-supervised learning framework was designed. In the framework, the idea of semi-supervised learning was first time used in IRT area to improve the robustness of latent trait estimation. To convert the observed response pattern to the continuous latent trait and approximate some continuous functions which were hard to specify mathematically, deep learning techniques were also introduced. The combination of semi-supervised deep learning and IRT model improved both accuracy and robustness of the parameter estimation for IRT on noisy data with weak constraint. The experimental results showed that the proposed framework adjust the biases contained in both students’ ability estimation and item parameter estimation for 2PL-IRT model.

Luc Paquette

University of Illinois at Urbana-Champaign

lpag@illinois.edu

ABSTRACT

Sequential pattern mining is a useful technique for understanding learning behavior. However, it can be challenging to select the most “interesting” patterns discovered through sequence mining. The work presented in this paper proposes an effect-size-based (ESB) method to help researchers identify temporally interesting sequential patterns. ESB is extended from the Temporal Interestingness of Patterns in Sequences (TIPS) technique [4] and distinguishes itself by 1) considering a different association direction between the sequential pattern usage and time, 2) providing a more interpretable ranking metric, and 3) providing a different ranking order for temporally interesting sequential patterns. Both ESB and TIPS are applied to interaction log data to demonstrate their differences in selecting sequential patterns.

Keywords

Sequential pattern mining, effect size, interestingness metric, learning behavior evolution.

1. INTRODUCTION

Sequential pattern mining (SPM) aims to find temporal relationships between events [1]. It is a useful tool to understand students’ learning behavior and becomes increasingly popular in the field of education [10, 18]. For example, SPM has been applied to investigate the evolution of cognitive and metacognitive behavior within a computer-based science learning environment [7], to understand students’ problem-solving behavior and to explore the associations among metacognitive monitoring, scientific inquiry skills, and task performance within game-based learning environments [4, 16].

Due to the exploratory nature of SPM, researchers need to expend considerable efforts to interpret them and obtain actionable insight for teaching and learning from the discovered sequential patterns [5]. However, the number of sequential patterns discovered through SPM may be huge, and, as such, it is inefficient and sometimes impossible to investigate these patterns one by one. To ease selecting patterns, researchers proposed interestingness metrics to rank sequential patterns or association rules [9].

There has been interest in the topic of temporal analyses of learning data [11], especially in the context of self-regulated learning [12].

Yingbin Zhang and Luc Paquette “An effect-size-based temporal interestingness metric for sequential pattern mining” In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 720 - 724

As such, patterns that vary across time may be particularly interesting because they may reveal additional information. For instance, the variation of pattern occurrences across time can be used to evaluate the effectiveness of learning support [7]. If the evolution of some sequential patterns in the group who received support from the environment is different from the group without support, the support may have effects on learners’ behavior. The evolution of sequential patterns may also provide insights into improving the learning environment. For example, if a sequential pattern beneficial for learning frequently occurs during the whole learning processes except for a particular period, what happens in this period may be interesting. Understanding events in this period may further inform designing intervention to prevent students from stopping this behavior pattern in this period.

In order to ease the selection of temporally interesting patterns, Kinnebrew, Segedy, and Biswas [5] proposed the Temporal Interestingness of Patterns in Sequences (TIPS) technique, an information gain-based approach, to rank patterns contingent on their variation across time. This research extends the TIPS technique by proposing an effect-size-based (ESB) method. ESB was applied to interaction log data of students’ using the Betty’s Brain learning environment [2] to demonstrate its relative advantages in identifying temporally interesting sequential patterns in comparison with TIPS.

1.1 The procedure of TIPS

TIPS firstly segments each student’s log file into n ordered bins (e.g., five ordered bins) with equal sizes [5]. Then, for each student, it calculates the occurrences (also known as instance values) of each frequent sequential pattern in each bin. Thirdly, it takes the occurrences of a pattern per bin per student as the feature and the bin number (e.g., 1, 2, 3, 4, 5) as the label and calculates the information gain (IG) of this pattern. IG refers to the reduction in Shannon entropy about the label from knowing the feature. Its calculation is [14]:

$$IG(L, F) = Entropy(L) - Entropy(L|F) \quad (1)$$

L refers to the label, while F refers to the feature. $Entropy(L)$ is the priori Shannon entropy about the label, while $Entropy(L|F)$ is the conditional Shannon entropy about the label given the feature. Finally, TIPS ranks all frequent sequential patterns based on their IG, and the top-ranking sequential patterns may be temporally interesting.

2. Effect-size based (ESB) temporal interestingness metric

2.1 The procedures of ESB

The ESB approach also needs the first two steps of TIPS, i.e., computing the occurrences per bin per student for each sequential pattern. However, in the next step, the ESB adopts the idea of

repeated-measures designs [13] and regards the occurrences of a pattern as a variable that is measured several times. One bin is one time. Under this framework, one-way repeated ANOVA can be conducted with the occurrences as the dependent variable and the bin number (i.e., the time) as the independent within-subject variable. Then, ESB calculates the effect size to characterize the association strength between the bin number and the occurrences of a pattern. The ESB regards the effect size as a temporal interestingness metric for sequential patterns. Given that the number of students and bins within a study is constant, the sample sizes for all frequent patterns are the same. Thus, the effect size is comparable across sequential patterns.

There are several effect size measures for ANOVA. Lakens [8] suggested using omega squared for comparisons of effects within a study. The meaning of omega squared is analogous to R squared in linear regression. It estimates the percent of variance explained by the independent variable (the bin in this case). For instance, an omega squared of 0.1 means that 10% of pattern occurrence variance can be explained by the bin number (i.e., time).

Omega squared is used for parametric repeated ANOVA. However, in practice, the distribution of sequential pattern occurrences may violate the assumptions of parametric ANOVA, such as the normality assumption and the homogeneity of variance. For example, some temporally varying sequential patterns may rarely happen at the beginning or end of learning activities. Their occurrence values have many zero in these periods, and their distributions are highly skewed. In this case, it would be better to conduct a non-parametric repeated ANOVA, such as the Friedman test. The effect size corresponding to the Friedman test is Kendall's W [17]. Its calculation is:

$$W = \frac{\chi^2}{N(k-1)} \quad (2)$$

χ^2 is the Friedman test statistic value. N is the number of subjects, and k is the number of measurements per subject. Kendall's W is interpreted similarly to omega squared and ranges from 0 (no relationship) to 1 (perfect relationship).

2.2 Differences between TIPS and ESB

2.2.1 Implicit assumptions.

The direction of the relationship between the occurrences of patterns and time is opposite in the two methods. TIPS examines the extent to which the occurrences of a pattern can distinguish different bins. In other words, TIPS implies that the occurrences of a pattern influence the bin number. In contrast, the ESB assumes that the bin number influences the occurrences of a pattern. While both approaches look at the evolution of the usage of patterns, ESB's assumption is more natural since the assumption is that the bin number is fixed, and the frequency of the pattern is what varies over time. Nevertheless, this distinction between the TIPS and ESB is conceptual and may not have a practical impact.

2.2.2 Interpretability.

The interpretability of ESB may be better than TIPS. As demonstrated above, the meaning of effect size (e.g., omega squared and Kendall's W) is straightforward. Besides, for researchers having experiences with ANOVA, they may already be more familiar with such measures of effect size. This characteristic of ESB can facilitate setting a threshold to filter patterns that may be less temporally interesting. For example, a general rule of thumb on magnitudes of Kendall's W is that W higher than 0.1 but smaller than 0.3 represents a small effect, W no less than 0.3 but less than

0.5 represents a medium effect, and W no less than 0.5 is a large effect [3]. If researchers are only interested in patterns that have at least medium variation across time, they can use 0.3 as the Kendall's W threshold to filter patterns. However, it is more challenging to decide the information gain threshold because the scale of information gains depends on contexts, such as the number of categories (i.e., the number of bins) of the label and the number of distinct values of the feature.

3. Application example

In order to demonstrate the differences of TIPS and ESB in identifying temporally interesting sequential patterns, they were applied to data from a recent study where 88 sixth-grade students learned climate change within Betty's Brain, a computer-based learning environment [2]. Students firstly received a training session on how to use Betty's Brain and used it to study climate change in the next four school days around 45 minutes per day. The action logs of students' working on Betty's Brain were analyzed. The output of TIPS and ESB were compared to investigate the relative advantages of ESB.

3.1 Betty's Brain

In Betty's Brain, students learn about scientific phenomena, such as climate change, by teaching Betty, a virtual pedagogical agent. They teach Betty by adding scientific concepts and directed causal links among the concepts on a blank page. Students can access hypermedia resource pages on relevant scientific concepts and causal relationships. Students can evaluate the causal links by asking Betty to take quizzes. By looking at Betty's correct and incorrect answers, students can identify problems in their understanding.

3.2 Data preprocessing

Firstly, irrelevant actions, such as actions initiated by the system, were removed from the raw action logs [6]. Then, actions were contextualized based on the duration and coherence. Viewing quiz results actions were labeled long vs. short, depending on whether the duration was higher than 3 seconds. Reading page actions were labeled long vs. short, depending on whether the duration was longer than 10 seconds. Long reading pages, adding, revising, and marking links were labeled coherent vs. incoherent, depending on whether these actions were based on prior actions [15]. Finally, the same consecutive actions were collapsed into a single action but labeled multiple. For example, two consecutive short reads were collapsed into an action named multiple short read.

3.3 Applying ESB and TIPS

Traditional sequence mining was applied to the preprocessed dataset to get frequent sequential patterns. The threshold for the support value was 0.5. The maximum gap was 2. This step resulted in 176 frequent sequential patterns. Then, each student's preprocessed log file was segmented into five bins of equal size. For each frequent sequential pattern, its occurrences were calculated per bin per student. Next, Kendall's W and IG of each pattern were computed. These patterns were ranked based on Kendall's W and IG, respectively.

3.4 Results

Some patterns had a high W-based ranking but a comparably lower IG-based ranking or a high IG-based ranking but a comparably lower W-based ranking. Table 1 presents the ranking, Kendall's W, and IG of four such patterns. *View notes* → *Multiple short read* and *Read short* → *Multiple incoherent read* were ranked in the top 10

based on Kendall's W, but 33rd and 35th based on IG. In contrast, *Short read* → *Coherent read* and *Taking a quiz* → *Prompt* → *Coherent revision* were ranked in the top 10 based on IG, but 37th and 39th based on Kendall's W.

Figures 1 to 4 use boxplots to display the occurrences of the four patterns in each bin. The evolutions of *View note* → *Multiple short read* and *Short read* → *Multiple incoherent read* was quite similar. Both their usage was more frequent in the first bin than in the others and had little variation among the four last bins. Forty percent of students made *View note* → *Multiple short read* in the first bin, while less than 16% of students made this pattern in the other bins. Similarly, thirty-four percent of students executed *Short read* → *Multiple incoherent read* in the first bin, but less than 12.5% of students did so in the others.

By contrast, *Short read* → *Coherent read* and *Taking a quiz* → *Prompts* → *Coherent revision* were less frequent in the first bin than the others. Thirty percent of students executed *Short read* → *Coherent read* in the first bin, but over 55% of students did so in the others. Twenty-five percent of students made *Taking a quiz* → *Prompts* → *Coherent revision* in the first bin, but over 40% of students did so in the others.

Note. 'x' indicates the mean. Dots are outliers within a bin, i.e., cases whose occurrences greater than 'the median + 1.5 * IQR' (distance between the first and third quartiles). Dots are jittered.

Figure 1. The boxplot of the occurrences of *View note* → *Multiple short read*.

Note. 'x' indicates the mean. Dots are outliers within a bin, i.e., cases whose occurrences greater than 'the median + 1.5 * IQR' (distance between the first and third quartiles). Dots are jittered.

Figure 2. The boxplot of the occurrences of *Short read* → *Multiple incoherent read*.

There are also similarities between ESB and TIPS. For instance, fourteen patterns were ranked in the top 20 most interesting patterns by both Kendall's W and IG, and ten patterns were ranked in the lowest 20 by both metrics.

Table 1. Four selected sequential patterns.

Pattern	W - ranking	IG - ranking	Kendall's W	IG
View note → Multiple short read	10	33	0.117	0.051
Read short → Multiple incoherent read	8	35	0.133	0.049
Short read → Coherent read	37	10	0.062	0.073
Taking a quiz → Prompts → Coherent revision	39	7	0.061	0.078

Note. 'x' indicates the mean. Dots are outliers within a bin, i.e., cases whose occurrences greater than 'the median + 1.5 * IQR' (distance between the first and third quartiles). Dots are jittered.

Figure 3. The boxplot of the occurrences of *Short read* → *Coherent read*.

Note. 'x' indicates the mean. Dots are outliers within a bin, i.e., cases whose occurrences greater than 'the median + 1.5 * IQR' (distance between the first and third quartiles). Dots are jittered.

Figure 4. The boxplot of the occurrences of *Taking a quiz* → *Prompts* → *Coherent revision*.

4. Discussion

This paper highlighted three differences between ESB and TIPS. The first one is that the implicit assumption of ESB may be more natural than TIPS. ESB assumes that the bin number (i.e., time) influences the occurrences of a pattern, while TIPS implies that the occurrences of a pattern influence the bin number (see section 2.2).

The second difference is the interpretability. It is easier to interpret the ESB metric (i.e., effect size) than the TIPS metric (i.e., IG). For instance, the Kendall's W of *View note* → *Multiple short read* and *Short read* → *Multiple incoherent read* was 0.117 and 0.133, respectively, and their IG were 0.051 and 0.049, respectively. A Kendall's W greater than 0.1 but smaller than 0.3 means a small effect [3], so the two patterns have small variation across time. However, it is hard to understand what an IG of 0.051 or 0.049 means as both the number of bins and the number of distinct values of pattern occurrences may influence the range of IG.

The results of the application example revealed the third difference: the rankings of sequential pattern based on the effect size and IG were different. This difference is understandable because the formulas for the effect size and information gain are quite different.

Based on Kendall's W, sequential patterns with more occurrences in the first bin and few occurrences in the others were ranked higher than patterns with fewer occurrences in the first bin and more occurrences in the others. By contrast, based on IG, the former was ranked lower than the latter.

Although for all the above sequential patterns, there is a big difference in pattern usage between the first bin and the others, Kendall's W prefers *View note* → *Multiple short read* and *Short read* → *Multiple incoherent read* because the variation of their occurrences across students (between-student variation) were small within each of bin 2 to 5. Recall that less than 16% and 12.5% of students made these patterns in bin 2 to 5, respectively. This means that most of their occurrence values were zero in bin 2 to 5. In contrast, many occurrence values of *Short read* → *Coherent read* and *Taking a quiz* → *Prompts* → *Coherent revision* in bin 2 to 5 was non-zero (over 55% and 40% of students did them, respectively), and their usage had higher variation within each of bin 2 to 5 than *View note* → *Multiple short read* and *Short read* → *Multiple incoherent read* (see Figure 1 to 4). In one-way repeated ANOVA, the between-student variation is an error term. Considering the error term, the variation across bins were higher for *View note* → *Multiple short read* and *Short read* → *Multiple incoherent read* than for *Short read* → *Coherent read* and *Taking a quiz* → *Prompts* → *Coherent revision*. Therefore, the former patterns had a greater Kendall's W than the latter.

IG prefers *Short read* → *Coherent read* and *Taking a quiz* → *Prompts* → *Coherent revision* because many of their occurrence values in bin 2 to 5 were non-zero, and the distribution of these non-zero values varied across bins. For example, the number of students that did *Short read* → *Coherent read* two times was the biggest bin 2, but the number of students that did this pattern four times was the biggest in bin 4. Knowing this occurrence differences of *Short read* → *Coherent read* among bin 2 to 5 could decrease the uncertainty about the bin number (the label). However, most occurrence values of *View note* → *Multiple short read* and *Short read* → *Multiple incoherent read* were zero in bin 2 to 5. Knowing their occurrences provided less information about the bin number than knowing the occurrences of *Short read* → *Coherent read* and *Taking a quiz* → *Prompts* → *Coherent revision*.

In summary, the ESB approach may assign higher rankings than TIPS to patterns with more occurrences in one bin but few and similar occurrences in the others, while the latter may assign higher rankings than the former to patterns with fewer occurrences in one bin but more and similar occurrences in the else.

Thus, ESB would be useful if the goal is to identify sequential patterns that mainly appear in only one bin. Such patterns may inform the intervention and learning design. For instance, both *View note* → *Multiple short read* and *Short read* → *Multiple incoherent read*, patterns that mainly occurred in the first bin, are generally considered as bad strategies in Betty's Brain. This suggests that students might not be familiar with how to utilize the resource page when they start using Betty's Brain to learn climate change. Therefore, the training session may need to teach students more about how to read the resource page effectively.

4.1 Next steps

The application of TIPS and ESB to the example data provided initial insights about the relative advantages of these approaches, but it is necessary to obtain a more comprehensive understanding of their differences in ranking sequential patterns. This goal will be achieved by conducting a larger scale investigation where TIPS and ESB will be applied to dataset from various learning environments. Such investigation will demonstrate under which situation one method has better utilities than the other so that researchers can make an informed decision about which approach is most appropriate given a research purpose.

While our preliminary application example suggests the utility of ESB to provide insights into improving learning intervention, the goal of the current paper was to propose a new methodological approach for mining temporally interesting sequential patterns. As such, further work will be necessary to leverage ESB to answer formal research questions, such as whether an intervention is effective [7].

ABSTRACT

There has been considerable interest in techniques for modelling student learning across practice problems to drive real-time adaptive learning, with particular focus on variants of the classic Bayesian Knowledge Tracing (BKT) model proposed by Corbett & Anderson, 1995. Over time researches have proposed many variants of BKT with differentiation based on their treatment of the underlying parameters: (a) general across student and questions; (b) individualized for students; and (c) individualized for questions. Yet at the same time, most of these variants are similar in that they utilize the same Hidden Markov (HMM) architecture to model student learning and share many of the same drawbacks, including less effective balancing between recent and historical student data and assuming that students learn at the same rate across all the attempts irrespective of if they get the question right. At the same time, these variants share the virtue of parameter interpretability, a virtue not seen in recent efforts to re-cast knowledge tracing as a deep learning problem.

This paper proposes a different architecture that replaces learning rate with recency weights which capture student improvement wholly through data rather than assuming constant learning across attempts and manages recent and historical data more appropriately while retaining the interpretability of BKT parameters. The proposed model was tested on multiple public datasets from ASSISTments and Mindspark and performed similarly to classic BKT model on unseen data.

Keywords

Intelligent tutoring system, Bayesian Knowledge Tracing, Student modelling, Hidden Markov Model (HMM)

1. INTRODUCTION

One of the most common forms of adaptivity in intelligent tutoring systems is mastery learning, where a system provides content on a skill until a student demonstrates they know the skill [8]. Most intelligent tutoring systems rely on “Knowledge Tracing” models which predict whether a student has learned a skill or not based on the interactions with the learning resources related to that skill within the tutoring system. Currently, most systems used at scale rely on Corbett and Anderson’s (1995)

Bayesian Knowledge Tracing (BKT) model or a close variant of it. Most of these models differ in their treatment of the parameters L_0 , G , S and T , but leave the basic structure of the underlying HMM model unchanged, and thus share many of the limitations and drawbacks of the BKT model (e.g. [7, 10, 9, 10]). Recently there have been some attempts to use deep learning-based models in education, termed Deep Knowledge Tracing (DKT) [6, 5]. Though DKT models have performance advantages over BKT, it is extremely difficult to interpret the implicit knowledge model. Khajah and colleagues [6] found that it is possible to make meaningful enhancements to BKT that bring its performance to the same level as DKT models.

In this paper, we propose an algorithm, MS-BKT (Multistate BKT) to address two particular shortcomings of the classic BKT model. First, BKT assumes a constant learning rate after each practice opportunity, irrespective of the student responses, which can lead to bias in estimating student mastery level. Second, BKT represents latent student knowledge as a binary variable with known and unknown states, which is a simplification and assumes that the probability of being in a state at step n depends only on the previous step $n-1$. We suspect that these assumptions limit the BKT model from considering the entire history of responses for students in a balanced manner by giving unproportionately high weight to the most recent attempt. The MS-BKT addresses these issues through two modifications:

- The MS-BKT model gives more weight to recent responses over older ones during the iterative Bayesian update in order to capture changes in student mastery level from data and excludes learning rate T so there is no assumption of fixed learning after each attempt. Please note that this paper uses ‘Recency’ weights differently than previous papers such as Galyardt & Goldin [3] or Gong et al., [4], where they used a decay function to down-weight the older attempts. In comparison, this paper incrementally increases the weight of the newer attempts.
- MS-BKT expands the knowledge node from the typical 2 states (‘Not learned’, ‘Learned’) to 21 states. Adding multiple states to the knowledge node allows MS-BKT to better capture complex sequences of correct and incorrect responses as multiple states make it possible to fine tune the knowledge level more granularly after each new observation than the 2 state model. Given that real world data can be very noisy, MS-BKT model estimates lead to smoother learning curves than classic BKT models.

Deepak Agarwal, Ryan Baker and Anupama Muraleedharan "Dynamic knowledge tracing through data driven recency weights" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 725 - 729

2. APPROACH

2.1 Classic BKT Model Architecture

Classic BKT employs a Hidden Markov Model (HMM) with a two-state ('Not learned', 'Learned') latent node representing student mastery level of the skill and a binary observed node indicating whether the student solved the question correctly or incorrectly as shown in Figure 1. The model assumes that the student can make the transition from not knowing the skill to knowing after every practice opportunity, fit as the learning probability $p(T)$. The model also incorporates the probability that the student may answer a question incorrectly despite knowing the skill (called slip) or may get the answer correct despite not knowing the skill (called guess).

The probability that the student knows the skill gets updated after every practice opportunity through the following equations –

$$p(L_{n-1} | C_n=1) = \frac{p(L_{n-1}) * (1-p(S))}{p(L_{n-1}) * (1-p(S)) + (1-p(L_{n-1})) * p(G)}$$

$$p(L_{n-1} | C_n=0) = \frac{p(L_{n-1}) * p(S)}{p(L_{n-1}) * p(S) + (1-p(L_{n-1})) * (1-p(G))}$$

$$p(C_n | L_{n-1}) = p(L_{n-1}) * (1 - p(S)) + (1 - p(L_{n-1})) * p(G)$$

$$p(L_n) = p(L_{n-1} | C_n) + (1 - p(L_{n-1} | C_n)) * p(T)$$

2.2 Multistate BKT Model Architecture

The architecture for MS-BKT, shown in Figure 2, is similar to that of classic BKT with two changes:

- The "knowledge node" consists of 21 states instead of 2 (Knowledge states are denoted by L_n^i where i is in range

0 to 20 and $\sum_i p(L_n^i) = 1$). 21 discrete states were selected as it was granular enough to give a precise estimate with manageable calculation overhead. The choice of number of states can be explored further in future work, including the possibility of a continuous distribution function.

- A recency weight parameter R is introduced in place of the transition probability $p(T)$. The model assigns a default weight of 1 to the first attempt and thereafter weight increases incrementally by a fixed quantum R for each new attempt. The optimal value of R can be learnt from data. Recent attempts are incrementally weighted more based on the intuition that the recent data will reflect current learning level better but at the same time, older attempts cannot be ignored completely as data can be inherently noisy.

This effectively means that MS-BKT is the same as classic BKT in that new data is integrated with a past estimate aggregating all past data, but differs in that the past estimate is now a distribution and that the weight of the new data increases over time.

$p(L_n)$ = Probability that the skill is known at n^{th} attempt
 $p(T)$ = Probability that the skill will be learnt at next opportunity
 $p(G)$ = Probability of guess
 $p(S)$ = Probability of slip

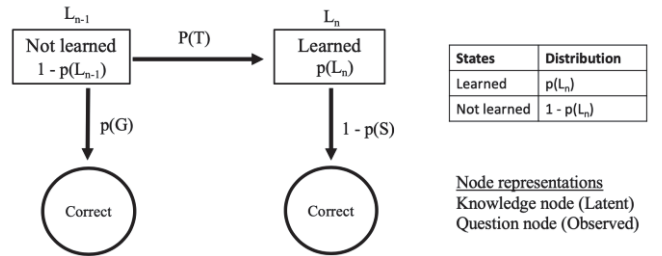

Figure 1. Classic BKT model

Figure 2. MS-BKT model architecture.

2.3 Updating Student Knowledge

Given an observation of the student's response at time opportunity n (correct or incorrect), updated student knowledge (L_n) is calculated using Bayes' rule. Since L_n now consist of 21 states, the probability of each state needs to be updated after every new observation as follows:

$$p(L_n^i | C_n) = \frac{p(C_n | L_{n-1}^i)^{(1+(n-1)*R)} * p(L_{n-1}^i)}{\alpha(\text{Normalizing factor})} \quad \text{For } i \text{ in range } 0 \text{ to } 20$$

Where:

- $p(L_n^i | C_n)$ represents the probability of the i^{th} knowledge state given the observation C_n
- $p(C_n | L_{n-1}^i)$ is the likelihood factor. $p(C_n | L_{n-1}^i) = L_{n-1}^i * (1 - p(S)) + (1 - L_{n-1}^i) * p(G)$
- $p(L_{n-1}^i)$ is the prior probability of the i^{th} knowledge state
- $1 + (n-1)*R$ is the weight for the n^{th} response, where n is the number of actions so far and R is a free parameter estimated during model fitting
- α is the normalizing factor which is computed at each iteration to be the value that ensures that probabilities across all the 21 states sum to 1

Once new probabilities are calculated, L_n value is estimated using maximum a posteriori probability (MAP) estimate that equals the mode of the posterior distribution. The advantage of using a MAP estimate over an EAP estimate is that it provides sharper updates

even at the initial responses stage. The overall model parameters are learned from data using 'Expectation Maximization'.

3. RECENCY WEIGHTS SUCCESSFULLY CAPTURES REAL TIME LEARNING FROM DATA

In this section we use a hypothetical example to show that the MS-BKT model is capable of capturing learning and forgetting from data itself by the property of recency weights and does not need an external fixed amount of learning to be added after each attempt, unlike classic BKT. This example tracks how the mastery level of three fictitious students changes as they attempt 10 questions on a skill for MS-BKT model. Parameter values used for the below illustration are as follows: L_0 : 0.5; G : 0.1; S : 0.1; and T : 0.3.

All three students answer five questions out of 10 correctly, but their patterns are different. Student1 answers questions correctly and incorrectly consecutively. Student2 answers more questions correctly in later attempts, whereas for Student3 the situation is reversed, suggesting that Student2 displays a learning behavior whereas Student3 displays forgetting.

As the following table shows, the mastery level estimate from MS-BKT for Student2 (pattern with learning) is considerably higher than for Student3 (pattern with forgetting), though both students answer 5 out of 10 questions correctly. The mastery estimate of Student1, which was added as a base case, is close to 0.5 as expected.

Table 1. Response patterns used for generating posterior distribution curves

	Q1	Q2	Q3	Q4	Q5	Q6	Q7	Q8	Q9	Q10	Mastery Estimate
Student1	0	1	0	1	0	1	0	1	0	1	0.55
Student2	0	0	0	0	1	0	1	1	1	1	0.67
Student3	1	1	1	0	1	0	0	1	0	0	0.37

4. OTHER OBSERVATIONS

In the BKT model, L_n values get updated very aggressively after each observation and result in large fluctuations in the value of L_n (though, with reasonable parameter values, BKT still has lower fluctuation than has been reported for DKT, e.g. Yeung & Yeung, 2018). In comparison to classic BKT model, the MS-BKT model does not fluctuate that widely for the same set of skill parameters. MS-BKT model also takes in account the entire history of the student's responses in a more balanced manner whereas in BKT, a student's response history prior to the third or fourth attempt may become irrelevant due to aggressive updates.

Table 2 and Figure 3 illustrate the above two points using fictitious student data. The underlying BKT and MS-BKT models use the same parameter values for L_0 , G , and S ; L_0 : 0.5, G : 0.1, and S : 0.1. T value for BKT model is 0.1 and R value for MS-BKT is 0.3. The comparison of L_n values for Student4, Student5, and Student6 show that L_n values have significantly higher fluctuations for BKT model in comparison to MS-BKT model. Also, in the cases of Student4 and Student7, L_n estimates are

extremely high for the BKT model and does not correspond to the respective response patterns. For Student4, L_n shoots up drastically to 0.75, even though there is a long history of incorrect responses on previous attempts and learning rate is only 0.1. By comparison, the L_n value is around 0.30 for the MS-BKT model. For Student7, L_n value is 0.83 in the case of the BKT model even though 3 out of last 4 responses were incorrect. This is largely due to the fact that the BKT model considers fixed learning rate irrespective of the student responses. The same L_n value for the MS-BKT model is 0.45, as the model is able to derive learning or forgetting directly from the data. Comparison of the response patterns of Student5 and Student6 shows some trade-offs between models. MS-BKT model estimates the L_n value to be 0.55 for Student6 in comparison to 0.90 estimated by the classic BKT model – probably a better fit, since the student has alternated between answering the questions correctly and incorrectly. By contrast, for student5 MS-BKT estimates L_n value to be 0.70 giving the student more credit as for recent responses being correct – perhaps a little too low compared to BKT. Of course, all of these estimates can be adjusted by tuning the parameters during model development.

Table 2. Response patterns used for comparing the two models

	Q1	Q2	Q3	Q4	Q5	Q6	Q7	Q8	Average	BKT	MS-BKT
Student4	0	0	0	0	0	1	0	1	0.25	0.75	0.30
Student5	0	0	0	0	1	1	1	1	0.50	1.00	0.70
Student6	0	1	0	1	0	1	0	1	0.50	0.90	0.55
Student7	0	1	1	1	0	1	0	0	0.50	0.83	0.45

5. PREDICTION QUALITY

We used 6 datasets across 2 different ITS (Assistments - G6_207, G7_233, G6_217; Mindspark - PER015, WNO021_57, WNO021_48) to compare the performance of the MS-BKT model against classic BKT model. Mindspark is an adaptive online tutor for Math and English, developed by Educational Initiatives (EI). Mindspark Math currently has 80,000 users across India, primarily from private schools, in grades 1 to 9. ASSISTments is an online tutor that supports student learning through the use of scaffolding, hints, and immediate feedback. All the datasets consist of student responses in the form of correct or incorrect answers from specific problems tagged by skill. The performance was compared on a hold-out data set consisting of 20% of the data. Table 3 lists out the parameter values for the two models for all the datasets using training data. The parameters for each model were tuned using the simple Brute Force approach. Table 4 compares the performance of both the models on hold-out dataset. Results show that the classic BKT model performs better than MS-BKT model on most of the datasets (except G6_207 and WNO021_57) but the differences are not very large.

6. CONCLUSION

This paper highlights two issues related to the classic BKT model and tries to address them by proposing a new model (MS-BKT). The paper demonstrates that applying a recency adjustment to Bayesian updates can lead to better properties of knowledge estimation, compared to using a static learning rate. The paper also proposes considering latent student knowledge as a multistate variable instead of 2 states, leading to smoother updates in the learning level estimate. In summary, the MS-BKT model displays some useful properties that are worth considering. Ultimately, models should both capture data well and have desirable properties for actual use, whether for use in a running system or discovery with models analysis. There is considerable future work to be done in refining the MS-BKT model further – such as selection of the appropriate number of knowledge states, implementation of recency weights, and effective ways to tune the model parameters.

ABSTRACT

A good diagnostic assessment is one that can (i) discriminate between students of different abilities for a given skill set, (ii) be consistent with ground truth data and (iii) achieve this with as few assessment questions as possible. In this paper, we explore a method to meet these objectives. This is achieved by selecting questions from a question database and assembling them to create a diagnostic test paper according to a given configurable policy. We consider policies based on multiple attributes of the questions such as discrimination ability and behavioral parameters, as well as a baseline policy. We develop metrics to evaluate the policies and perform the evaluation using historical student attempt data on assessments conducted on an online learning platform, as well as on a pilot test on the platform administered to a subset of users. We are able to estimate student abilities 40% better with a diagnostic test as compared to baseline policy, with questions derived from a larger dataset. Further, empirical data from a pilot gave an 18% higher spread, denoting better discrimination, for our diagnostic test compared to the baseline test.

1. INTRODUCTION

Learning theory is an important field of research, which incorporates insights from such diverse fields as psychology, pedagogy, neuroscience, and computing to model how well a student learns the taught information. Insights from learning theory are applicable in a wide variety of applications, such as creating intelligent tutor systems and learning platforms, designing courses, designing test papers for exams, and teaching a learner a skill. A prerequisite for any of these activities is to diagnose the current skill level of a new student. This is akin to the *cold start problem* in recommender systems. One proven technique to assessing the current skill

level of a new student is to use a set of assessment challenges, most commonly taking the form of a test paper. A good test paper is one that has specific characteristics in terms of *accuracy* and *discrimination*: The test paper should be able to *accurately* diagnose the ability level of a student for the skill set being evaluated, and it should be able to *discriminate* between students of different abilities. Additionally, it should be able to meet these objectives using as few questions as possible.

Figure 1: (a) A test in which students of different abilities perform similarly, i.e. get similar scores, is not a good test (b) A better test which can discriminate between students of different ability

If a test paper has questions that many, or all, students answer equally correct or wrong, it will not provide any meaningful information about students. An ideal test paper would reflect student performance such that students with low ability level would get fewer questions correct (lower marks scored) while students with high ability level would get more questions correct (higher marks scored) Fig. 1 illustrates both types of test papers.

In this paper, we present an approach to select questions from a question bank, using configurable policies, that meet the above criteria. We use the selected questions to create a test paper. We then evaluate the generated test paper as per the criteria of accuracy and discrimination, and thus decide on the *goodness* of the policy. Finally, we validate the generated test paper with the best policy on a pilot study of students attempting the test paper. The rest of the paper is organized as follows. Section 2 looks at related work in test paper generation. Section 3 describes our approach to model the problem. Section 4 outlines multiple policies to select questions to compose a test paper. Section 5 discusses the quality evaluation criteria. Section 6 discusses and analyses the results on the simulated and pilot test papers. Finally, Section 7 concludes the paper and presents directions for future work.

2. RELATED WORK

Soma Dhavala, Chirag Bhatia, Joy Bose, Keyur Faldu and Aditi Avasthi "Auto generation of diagnostic assessments and their quality evaluation" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 730 - 735

Cen et al. [1] described the architecture of an automated test generation system, using random selection and other strategies to generate questions. They focused on the architecture and not on the effectiveness of the selected questions in diagnosing student ability. A number of studies have been performed on the effectiveness of adaptive test generation, using algorithms to select test questions dynamically from a given pool. Linacre [2] surveyed computer adaptive testing (CAT) in relation to its history and advantages such as needing fewer questions and a shorter time frame than classical tests to diagnose a student's skill level. The questions are selected from a question database, and models such as the Rasch model (a variant of the popular item response theory (IRT) model [3]) are used. CAT starts by presenting questions with average calibrated difficulty at first, then increasing or decreasing the difficulty level of subsequent questions depending on whether the student got the answer right or not. This continues until the system has reached a good estimate of the student's true ability. CAT testing has limitations such as restrictions on re-calibration if the student changes their mind about a previous answer. Another limitation is that the calibration methodology is based on a single parameter, that of difficulty, and not other parameters such as behavior. Kingsbury [4] suggested an approach to improve the adaptive calibration process in a CAT test by considering the student's momentary trait level estimate, in addition to item difficulty, while selecting questions. Also, the estimated difficulty of each question, initially tagged by experts, is continually calibrated based on how many students have answered correctly in the tests given. They found this approach yielded better results in estimating the difficulty of an item. Makransky [5] compared calibration strategies for test questions, including a random strategy and a strategy where the questions are calibrated at the end of a phase or multiple phases, in order to estimate the item difficulty accurately. They implemented the strategies on 1PL and 2PL models of IRT, and found that a continuous updating strategy performed best. Wim [6] surveyed student ability estimation as well as item selection for CATs, using models such as Maximum Likelihood and Bayesian criteria to estimate ability and mean absolute error as the evaluation parameter. Our paper also uses similar models, and additionally realtime data of administered tests to evaluate the accuracy of the models as well as the discrimination ability.

Some researchers have studied factors other than item difficulty when selecting questions. Liu et al [7] found that behavioral factors such as test-taking motivation in students can play an important role in determining learning outcomes. Similarly, Tsousis [8] suggested a variant of the IRT model in which behavioral parameters like item response time can be incorporated. In another study on behavior as a factor, Jaworski [9] discussed the calibration of control questions in a personalized polygraph test, using emotion and behavior as parameters in selecting the questions. Daroudi et al. [10] surveyed reinforcement learning as a strategy to model the sequencing of instructions in order to maximize learning.

3. PROBLEM FORMULATION

For our analysis, we use a question database taken from Embibe, an online learning platform, along with responses from a set of students on each question. The student's abil-

ity is a latent variable, which when estimated with statistically adequate data samples gives a better estimation of the ground truth. For this paper, we consider the ability derived from a larger dataset (in this case, the question database) as ground truth, and abilities derived from a single test as the predicted abilities. For each question in the database, we have the following parameters: Discrimination factor, Difficulty level, Chapter number (represents the chapter number in the syllabus which the question comes from) and Student behavior data for the question. For each student, we have the Ability and Discrimination factor parameters (from the fitted IRT model). The difficulty level and chapter number of each question are annotated by human experts. The anonymized data related to the student responses is collected by the platform.

Out of this ground truth dataset, our objective is to select a subset of questions to assemble into a test paper, which meets the criteria such as best discriminative ability and best match of the identified student ability with the ground truth.

θ : Student Ability
 α : Discrimination
 β : Difficulty
Ch: Chapter

Figure 2: Ground truth dataset of questions taken of a learning platform, with IRT parameters and chapter information

Fig. 2 illustrates the ground truth dataset of questions, along with data on the correctness of students' past responses on each question (whether they answered the question correctly or not). Out of this matrix, we select a small subset of exam questions that can discriminate between students of different abilities.

As per the Item Response Theory (IRT) model, for each question we have a measure of its difficulty and discriminative ability, as well as a measure of the student ability for each student. The standard IRT model gives a relation between the ability and the difficulty, based on one or more parameters and predicts the likelihood that the student will answer that question correctly. We use the 2PL IRT model to calibrate and evaluate our generated test papers.

As per the 2PL IRT model, the probability or likelihood of the student answering a question correctly is given by the following equation:

$$P(X = 1|\theta, \alpha, \beta) = \frac{e^{\alpha(\theta - \beta)}}{1 + e^{\alpha(\theta - \beta)}} \quad (1)$$

Here, θ represents the student's skill/ability level, α represents the discrimination factor of the question, β represents the difficulty level of the question and P represents the probability that the student will answer correctly.

We infer the IRT model parameters (α, β, θ) from our ground truth dataset by fitting a fully connected deep neural network (modeled using Keras [11] library). The inputs to the neural network are one-hot encodings of the student and question vectors, and the output is the correctness of the student's response for that question, which is a binary value. The IRT parameters are estimated by fitting the neural network using Binary Cross Entropy (BCE) loss. The fitted model is scalable and can handle missing data and imbalanced classes very well. Fig. 3 shows the architecture of the deep neural network for 1PL IRT model. Other IRT models can be realized using the same template.

Figure 3: Neural network architecture for estimating 1PL IRT parameter values.

Our problem of selecting an optimal set of questions to form a test, following various constraints, can be modeled in the following manner: Let A be a K -dimensional tensor of size n_1, n_2, \dots, n_K . Each entry of this tensor is either 0 or 1 indicating whether a question with a particular set of attributes was sampled or not. Each dimension of this tensor represents a question attribute, such as a *chapter number*, *difficulty level*, etc. For example, let us say we are interested in creating a test such that four chapters are to be covered, with difficulty levels ranging from 1-10. Then we have $n_1 = 4, n_2 = 10$. Here $A[i, j] = 1$ means that we select a question from chapter i with difficulty level j . We can then set constraints on this tensor to reflect some desired characteristics. For example, the following constraint says that there has to be at least one question from each chapter.

$$\sum_j A[i, j] \geq 1$$

Likewise, we can say that difficulties should follow a certain distribution. Let d_j be the number of questions we like to have whose difficulty level is j . Then,

$$\sum_i A[i, j] = d_j$$

Now we can count how many times the above condition is not met, as a way to measure the quality of the assignment/sampling. Using this, we can form an objective function that evaluates how well the chosen test reflects the above loss, which simply counts the number of disagreements.

$$\min \sum_j I(\sum_i A[i, j] \neq d_j)$$

The above objective function is zero when conditions are met exactly (hard constraint). We can generalize this idea

to include constraints about all the question attributes (that are factor variables). Let there be n_k levels for the k -th dimension of the tensor A . These levels represent, for each attribute, the range of values that attribute can take. Let $d_{k(i)}$ be the number of questions needed where the question's k -th attribute has level $c_{k(i)}$. Notice that different attributes can have different number of levels.

$$\min \sum_{k=1}^K \lambda_k \sum_{i=1}^{n_k} I(\sum A^k[i] \neq d_{k(i)})$$

Here $\sum A^k[i]$ means that, we select the k -th dimension of the tensor, and its i -th cube, and summing along the cube. In particular, when $\forall_{k(i)} d_{k(i)} = 1$ then Latin HyperCube sampling can be used. The above objective can also be used as a fitness function in genetic algorithms or other search techniques, both stochastic and deterministic, to allocate questions to a test paper. λ_k is a weight parameter which we can tune, for our purposes in this paper we set all the values of λ_k to be equal.

The above objective function, which can be coupled with other IRT based test design objectives, is dealing with domain constraints. Test designs that consider the variance-covariance matrices of parameters in the IRT are also widely used[12]. In particular, the relationship between the item difficulty, discrimination and ability has been addressed from a D-optimality sense. Based on those insights, we formulate a theorem along with proof as below. This is used to develop one of our question selection policies.

THEOREM 1. *In a 2PL IRT model, when the difficulty of an item is close to the ability of the person, an item with high discrimination will have high information, and is locally D-optimal.*

PROOF. The Item Information function for the 2PL IRT model introduced earlier is given as:

$$I(\theta; \alpha, \beta) = \frac{\alpha^2 e^{\alpha(\theta-\beta)}}{(1 + e^{\alpha(\theta-\beta)})^2}$$

The above equation can be rewritten as:

$$I(\epsilon; \alpha) = \frac{\alpha^2 e^{\epsilon\alpha}}{(1 + e^{\epsilon\alpha})^2}$$

where $\epsilon = \theta - \beta$. Let us consider another item with higher discrimination $\alpha' = \alpha + \delta, \delta > 0$, but with difficulty close to the ability. Then,

$$\lim_{\epsilon \rightarrow 0} \frac{I(\epsilon; \alpha')}{I(\epsilon; \alpha)} = \left(\frac{\alpha + \delta}{\alpha} \right)^2 > 1$$

Hence, an item with high discrimination will have higher asymptotic relative efficiency, when the difficulty is in the neighbourhood of the ability. We can claim that such a policy is D-optimal. \square

4. TEST PAPER GENERATION

In order to generate a test paper, we propose a set of candidate policies to select questions from the ground truth dataset and assemble the selected questions to form a test paper. All policies assume that the syllabus is covered adequately, i.e. questions are selected from each area of the

syllabus. Based on theorem 1 and [12], we select questions with a mix of difficulty levels. We evaluate these policies as per their effectiveness in distinguishing students. To evaluate each policy, we measure parameters such as spread of the scores obtained by different students on the test and how well the diagnosed abilities of the students correspond with the ground truth abilities (by computing the Mean Square Error, Spearman's Rank Correlation and a scatter plot of diagnosed ability vs. true ability). We then choose the best policy to generate a test paper to validate our model by testing on a real world group of students using the same online learning platform where we sourced the ground truth dataset. Fig. 4 shows a flowchart illustrating this method.

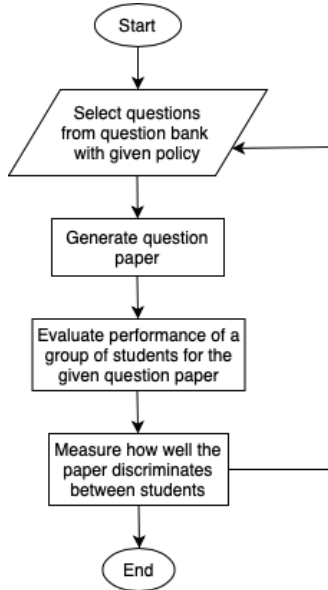

Figure 4: Flowchart showing a method to generate test papers from a question bank by selecting questions using a configurable policy, and evaluating how well the policy diagnoses different kinds of students

The candidate policies are described in the following subsections.

4.1 Baseline policy π_{BSP}

As a baseline, we select N questions from the ground truth dataset, by randomly selecting over other question attributes after ensuring a mix of difficulty levels and syllabus coverage. This selection of questions becomes our standard baseline - **BSP**.

4.2 Discrimination only policy π_{DOP}

We use the discrimination parameter values inferred from the fitted 2PL IRT model. We select questions with a mixture of difficulty levels, and the highest values of the discrimination factor for each given difficulty level. We select N questions from the ground truth dataset, ensuring syllabus coverage (at least one question from each chapter), but also ensuring that the overall discrimination factor of the questions is maximized. This policy, **DOP**, ensures that high discrimination questions are selected, at any given difficulty level.

4.3 Discrimination+behavior policy π_{DBP}

In this policy, we incorporate behavior parameters along with discrimination, difficulty and syllabus coverage, while selecting questions. Behavior parameters refer to the student behavior when taking the test, captured by the learning platform. These include parameters such as number of questions that are likely to be answered too fast and incorrectly, or questions that are answered too slow but correctly, among others. The questions are tagged as per which parameters are mostly manifested by students answering that question and the top questions from each parameter are selected. This policy, **DBP**, ensures that high discrimination questions as well as student behavior are taken into account.

5. QUALITY EVALUATION CRITERIA

In order to evaluate the generated test papers, we use two criteria: *accuracy* and *discrimination*. *Accuracy* refers to how closely the diagnosed ability using the student responses to the test paper corresponds to the actual ability of the students. We use the RMSE between the ground truth and the inferred ability as a measure of the accuracy. The rank correlation between the ground truth rank and the estimated rank, and scatter plot between the inferred and ground truth ability, also indicate the accuracy.

Discrimination measures how successful the test paper is in discriminating between students of different abilities. We evaluate the accuracy and discrimination for the generated test papers on a subset of M students (evaluation student set) from our ground truth dataset. We use the spread and distribution of scores as a measure of the discrimination.

Evaluation using RMSE

Using the IRT model, we predict the probability of each student in the evaluation set answering the questions correctly, and compute the average ability from the scores of the students if they were to attempt the generated test paper. We also determine the ground truth ability of each student from the IRT model. Finally, we compute the root mean squared error (RMSE) between the ground truth ability and inferred ability to get a measure of the accuracy.

Evaluation using Spearman's ρ

Here we sort the abilities of students obtained from the ground truth data and from the generated test, and determine the rank correlation ρ between the two ranks.

Evaluation using scatterplots

We plot the abilities of students, inferred from the ground truth, against the diagnosed abilities from the generated test papers. The degree of scatter gives an indication of how much the ability matches the inferred ability.

6. RESULTS AND DISCUSSION

We have an initial ground truth dataset, obtained from the online learning platform, of close to 1300 questions and 1700 students along with the responses for each of the students on each question, along with the derived IRT parameters. From the dataset, we filter those students who have attempted less than 25% of the questions in each paper, so that we have sufficient data to estimate their abilities.

6.1 Simulated tests

We choose 75 questions from the ground truth dataset for each policy, in effect simulating a test of 75 questions. In selecting the questions, we ensure syllabus coverage. Table 1 shows various test statistics.

Table 1: Comparison of test results from simulated tests generated by the three policies

	BSP	DOP	DBP
No. of students	312	312	312
No. of questions	75	75	75
Max. score possible	300	300	300
Max. score achieved	188	251	218
Min. score achieved	-22	-17	-23
Score at 95th percentile	118.4	148	144.5
Score at 5th percentile	3	4	0
Avg. score achieved	60.80	79.25	77.18

Fig. 5 shows the comparison in spread of student scores for the simulated tests on test papers generated using the three policies.

Figure 5: Comparison of the spread in score obtained from the simulated tests generated using following policies: BSP, DOP and DBP.

For each of the test papers selected using different policies, we evaluate the accuracy and discrimination as mentioned in the previous section. We also calculate the ability of each student from the remaining questions in the ground truth dataset, which are not included in any of the generated test papers.

Table 2: Comparison of RMSE (inferred ability and ability from ground truth) and rank correlation ρ in tests generated by different policies

Policies	RMSE	Rank corr ρ
BSP	0.844	0.59
DOP	0.549	0.83
DBP	0.615	0.788

We find that the DOP test gives 24.8% better spread of scores (score at 95th percentile of students - score at 5th percentile), as compared to the BSP baseline. DBP test gives 25.2% better spread. The mean squared error for the inferred ability of the students compared to the ground truth ability is 0.844 for the BSP, 0.549 for the DOP and 0.615 for DBP. Table 2 shows the comparison between the policies

with respect to root mean square error (RMSE) and Spearman rank correlation. We obtain a 40% higher correlation for the DOP policy as compared to BSP.

Figure 6: Scatterplots of the abilities of the generated test papers, against the ground truth abilities. Degree of scatter is highest for the BSP paper

Fig. 6 shows a scatterplot of the abilities of the student from the test papers using the three policies, plotted against their ground truth abilities. We can see that the paper generated using BSP policy has the highest degree of scatter and the DOP paper has the lowest, i.e. it most closely matches the ground truth abilities of the student.

6.2 Analysis of the simulated test results

Comparing the policies from the score distribution in the generated test papers, we can see that the DOP and DBP policy give a better spread of scores than BSP, meaning they are better in discriminating between students of different abilities. Tests generated by both DOP and DBP policies also had a higher rank correlation than the BSP test, meaning we get a better accuracy at diagnosing the ability of the students.

The DBP test had a lower spread and lower rank correlation as compared to the DOP test. This could be because we only used the standard 2 PL model of IRT, without any modifications to include behavior parameters. Moreover, behavior parameters, such as time spent not attempting questions, give a more holistic view of how the student performs in a test (such as indicating the confidence level of the student) than simply the academic performance i.e. how many questions the student answered correctly. Perhaps future test papers could be designed in a way that takes into account these factors when computing the student's score.

6.3 Pilot test

To further validate our model, we conducted a pilot study as follows: We selected a group of M students and asked each student to attempt two test papers, using the same online

Table 3: Comparison of pilot test results generated by BSP policy and DBP policy

	BSP	DBP
Number of students	98	99
Number of questions	30	30
Max/Min/Total score	92/0/120	111/-1/120
Score at 95th/ 5th percentile	76/5	85/1
Average score	43.94	42.56

Figure 7: Scores distribution of students in the DBP generated pilot test vs BSP pilot test

learning platform we used for the earlier test generation. For the first paper, we generated the questions using BSP policy and for the second, we generated the questions using DBP policy. We then compared the spreads of scores for these test papers. The results are shown in table 3.

On the pilot test papers generated using the two policies, we found that the DBP test gives 18% higher spread of scores (95th percentile score - 5th percentile score), as compared to the BSP test. The mean squared error for the inferred ability of the students compared to the ground truth ability was 1.08 for the BSP test, and 0.86 on DBP. This is 20% less RMSE for DBP compared to BSP. From the scatterplots in

Figure 8: Scatterplots of the inferred abilities of the pilot test papers, against the ground truth abilities

fig. 8 for the inferred vs ground truth ability, we can further confirm that the degree of scatter is lower in the DBP pilot test and higher in the BSP pilot test paper. This confirms that the DBP test paper more accurately reflects the ability of the student, and is also better at discriminating between students of different abilities. The spread of scores in the DBP is better than that of the BSP policy. This validates our findings from the simulated tests, where also we obtained

a better spread for the diagnostic policies (DOP and DBP). Moreover, the higher accuracy of the inferred ability for the DBP pilot test is confirmed by a lower value of the RMSE and lesser degree of scatter compared with BSP.

7. CONCLUSION AND FUTURE WORK

In this paper, we proposed a few policies to generate test papers by selecting a list of questions from a question database. We validated the policies by a pilot test of test papers generated using two policies. We found that the policy of selecting questions based on highest discrimination ability for a given difficulty level yielded the best results.

In future, we intend to extend the IRT model to include behavioral parameters and further validate our method of selecting policies with more candidate policies and a larger sample size of students.

8. ACKNOWLEDGMENTS

The authors express their gratitude to Anwar Sheikh and his team for helping us conduct the pilot study.

Differential Responses to Personalized Learning Recommendations Revealed by Event-Related Analysis

Kevin C. Dieter

research@lexialearning.com

ABSTRACT

Educators are increasingly embracing personalization in online and blended learning programs as a means of focusing students' investment of time and energy into learning plans that are best tailored to their individual needs. When personalized learning tools are deployed into structured learning environments like schools, however, educators and students must consider program provided recommendations alongside potentially immutable factors like set daily schedules, mandated curricula, and student needs in other content areas. These on-the-ground factors make researching the impacts of personalized learning challenging because they are difficult to measure directly, especially for digital programs deployed at scale. Inspired by a widely influential methodology in brain imaging, we tackled this challenge by employing an *event-related* approach that emphasizes changes in student behavior that are time-locked to changes in program provided usage recommendations. Our analysis reveals that while student usage time can often be quite far from the amount recommended, students nevertheless respond to changes in program recommendations by adjusting usage in a corresponding manner. We further extend this general approach to demonstrate that students more often stayed on track toward their end of year goals following a week where they met or exceeded their program provided recommendation. Through these examples, we demonstrate the value of an event-related approach towards understanding how personalized paths can positively influence student learning.

Personalized learning, event-related analysis, time management, K-12 schools, personalized recommendations.

1. INTRODUCTION

As schools and communities embrace a rapidly changing world, a growing emphasis on the personalization of learning has emerged [10]. Learning is considered personalized if it is tailored to each learner's strengths, needs, and interests, encouraging flexibility in a student's pursuit of mastery and enabling learners to take an active role in what, when, where, and how they learn [22]. In the competition for instructional time, personalized learning approaches also hold the promise of helping students achieve mastery as efficiently as possible [10], and can facilitate

educators' work in guiding students' learning efforts towards educational activities that best match their current needs.

Online and blended learning programs are uniquely positioned to enable personalized learning because they can support student agency through independent pacing, delivery of differentiated content and support, and the ability to engage with learning anytime and anywhere [22]. However, the double-edged sword of personalized learning is that "the process of personalization puts enormous pedagogical and procedural burden on the students—as well as teachers—to make critical instructional decisions" [4; also see 5]. This includes decisions about how much time students should spend on specific programs and components of programs to maximize learning. While studies often find that students fail to spend as much time in educational technology programs as recommended by the program or researchers [23], students can also over-use, spending time on one set of activities that might be better spent in other areas.

One response from the designers of learning technologies has been the inclusion of embedded recommendations and self-monitoring tools to scaffold student and teacher support for self-regulation. Recommendations are tailored to help students and teachers make good decisions within a personalized learning environment without enforcing rigid requirements that may reduce student agency and be unrealistic for particular educational contexts. Individualized usage time recommendations do not appear to be common in most learning technologies; many continue to provide one-size-fits-all usage recommendations [9]. However, they hold the promise of facilitating self-pacing by helping students who are at different levels and progressing at different speeds to stay on track toward reaching their goals.

Despite the recognition of learning scaffolds as critical and effective for self-regulation in general [15] and in computer-based learning environments in particular [27, 28], relatively little research has been done into the impacts of recommendations. While the desire to enact personalization grows, the reality is that many educational institutions, particularly K-12 schools, continue to look much as they have for the past century, with set daily schedules and highly-regulated or mandated paths through content material [10]. When individualized learning tools are deployed into schools with structured learning environments, educators and students must consider program provided recommendations alongside these potentially immutable factors. While a program may recommend a different usage time to individual students within the same class or to the same student in different months, they may be unable to follow those recommendations with fidelity because of set schedules of technology access [25], challenges associated with implementing flexible learning time [20], or teacher and parent beliefs about learning technologies and screen time [6, 18]. Furthermore, researchers often have data on the usage recommendations a student received and their time spent

Kevin Dieter, Jamie Studwell and Kirk Vanacore "Differential Responses to Personalized Learning Recommendations Revealed by Event-Related Analysis" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 736 - 742

using the program, but lack direct insight into the specific contexts in which the program is implemented [26].

We addressed this research challenge by examining how students respond to personalized usage time recommendations within *Lexia® Core5® Reading* (hereafter “Core5”) - a blended learning literacy program that provides instruction in foundational literacy skills for students in grades preK-5. To isolate the impacts of program provided recommendations from the largely unknown aspects of school context, we model an analytic approach after one widely used in the field of brain imaging - *event-related design* [for a general overview see 12, 13; for a widely-cited early example see 11]. The key aspect of this methodology with respect to our present application is that we focus on *changes* in actual student usage time that occur time-locked to *changes* in personalized recommendations. That is, we ask how student behavior *responds* to changes in program suggestions rather than whether it is *aligned* to recommendations, as consistent student responses to changed program recommendations could be observed even if baseline student usage is widely variable across diverse school contexts. Utilizing this approach, we find that students indeed adjust the amount of time per week that they spend using Core5 in a manner that differentially relates to the direction and magnitude of the recommended change. We also extend our analysis to examine events defined directly by student behavior and find that the act of meeting one’s recommendation in a given week is associated with more frequently staying on track toward end-of-year goals in future weeks. Together, these examples highlight the power of an *event-related* approach, and reveal positive associations between the personalization of learning and student progress within school contexts.

2. DATA

2.1 Usage time recommendations in Core5

To personalize the learning path for each individual student, Core5 recommends a number of minutes per week that the student should use the online portion of the program, promoting regular, right-sized use and proactive time management throughout the school year to enable student success [7]. Each student’s usage recommendation reflects the estimated amount of time needed to reach their end of year “benchmark” - that is, to complete all program content for their grade level by the end of the school year. It is based on a predictive model that takes into account a student’s current place in the program, the amount of material left for them to reach their benchmark, and their time spent and progress made in the prior month [16]. These recommendations are shared prominently with educators in the program’s online data portal, and are visible to students while logged in to Core5.

Critically, student usage recommendations are not fixed throughout the school year, but are recalculated at the start of each month to reflect student progress and pace (see Figure 1). At the start of the year, before enough data has been collected to personalize recommendations, all students are set to a default recommendation of 40 minutes per week. At the start of the next calendar month (first Monday), a student’s recommendation changes to 20, 30, 50, or 60 minutes per week. With the beginning of each new month, a student’s usage recommendation is recalculated, resulting in either an additional change or a static recommendation. This cadence was chosen to allow regular revisions that reflect student’s usage and progress, while still remaining implementable for teachers. The goal in personalizing and updating these recommendations is that students use the

program enough to stay on pace to end the year at their grade level benchmark, without spending more time than necessary that could be invested in other learning activities. Previous research has shown that students who consistently meet recommended usage in Core5 make more progress and more often reach their grade-level benchmark than those students who infrequently or never meet their usage recommendation [17].

Figure 1: Usage recommendation profiles for two example students. Each line illustrates how usage recommendations for an individual student change across the time frame under study. Student 1 began the school year in early August, and like all students was initially recommended 40 minutes per week. On the first Monday of September, Student 1’s recommendation changed to 50 minutes per week, and at the start of October it was adjusted again to 60 minutes per week. Student 2 was also initially set at 40 minutes per week, but began the school year later (in mid-September). Following the same rules, however, Student 2’s recommendation was adjusted at the start of the next calendar month (October) to 30 minutes per week. For this student, the recommendation remained there for the duration of this time frame.

2.2 Sample Details

Weekly usage records for Core5 students in Kindergarten through 3rd grade were used for the analyses presented in this paper. Although Core5 also provides usage recommendations for pre-K, 4th, and 5th grade students, the specific time values differ for these grade levels. We therefore restricted our sample to K-3 students for clarity of interpretation, though we anticipate that results would be similar for students in other grades.

To obtain the records, schools were chosen at random from among those who had at least one student using Core5 in the fall of 2018 (total of 168 schools chosen). These schools were geographically diverse, located across 39 US states and 4 Canadian Provinces. Student-level demographic data is unavailable for this dataset. All weekly Core5 usage records between August 6, 2018 and December 31, 2018 were obtained for all students at these schools. To be included in the final

sample, students must have used Core5 for at least 7 weeks within this date range, and had their usage recommendation change at least once (as described in Section 1, the goal of the event-related approach is to focus on these changes). In addition, students who met their end of year benchmark (completed all grade level material) within this timeframe were excluded (this sets ones' usage recommendation to 0 minutes per week). Furthermore, students must have had a usage target of 40 minutes in their first week of program use within this timeframe. As previously described, Core5 assigns a default recommendation of 40 minutes per week during a student's first month of use in a school year, and any other value at that time point is an indication that there was a manual override (this is rare - 0.9% of students in our sample - but an available option for educators). The final sample contained 10,851 students (2,838 in Kindergarten; 3,213 in 1st grade; 2,836 in 2nd grade; 1,964 in 3rd grade). To ensure that these exclusion criteria did not produce non-representative results, we ran robustness checks using different cutoffs for minimum weeks of program use (6 or 8) and repeated our analyses with two additional samples of students based on new random selections of schools. We found that all results were qualitatively consistent with our reported findings.

The weekly Core5 records obtained contain aggregated usage data for each week that a student logged into the program. The metrics collected that are relevant to the presented analyses include the total time of Core5 use during that week, the recommended use time for that week, whether or not a student met their recommendation (total time greater than or equal to recommended time), and the Monday date of the week reported.

3. RESULTS

3.1 Alignment to usage recommendations

Our primary research aim is to assess whether students' usage time is responsive to Core5's personalized recommendations. Before presenting our results, however, it is critical that we distinguish this question of students' *responsiveness* to personalized recommendations from a related question about *alignment* between recommended and actual usage time. Specifically, we could observe changes in actual Core5 usage following a change in the program provided recommendation (i.e. a personalized *response*) without necessarily finding that students used the program for a particular number of minutes that is close to their recommended value (i.e. *alignment*). Indeed, because Core5's personalized recommendations serve as only one factor within the school context, it would not be surprising if a student's usage time in a given week was quite far from their personalized recommendation value, and more closely related to unknown (from a researcher's perspective) contextual factors such as the amount of time dedicated in their school's schedule to literacy learning or student-directed after school usage. Critically, even if there is poor *alignment*, we may find that when recommendations are changed that students' time spent using the program systematically adjusts in a manner consistent with those changes - a result indicative of responsiveness to Core5 recommendations.

We indeed find that alignment between Core5's usage recommendations and actual student usage time is weak. Although most students had a mean weekly usage time that fell within the range of Core5 recommendations (Figure 2, top panel; 70.0% of students with weekly mean between 20 and 60 minutes), there was a small negative correlation between actual and recommended program use time in aggregate (Pearson $r = -0.117$; 95% CIs = -

0.137, -0.098). Honing in on a snapshot of one particular week in our dataset (Figure 2, bottom panel), it is evident both that there is poor alignment to recommendations, and that there is widespread individual variability in usage time. While the average within-student mean for actual and recommended usage time were similar (46.2 and 43.3 minutes per week, respectively) the across-student standard deviations for these metrics were widely disparate (SDs = 22.9 and 11.1 minutes, respectively).

Figure 2: Distributions of students' Core5 usage time. (top) Though mean weekly usage across students was in a range similar to Core5's usage recommendations, there was a notable extent of individual variability. **(bottom)** A snapshot of the distribution of actual use (y-axis) for students with each unique recommended usage time during a particular week (x-axis) revealed no apparent relationship between the two. The data shown is for one example week that had the largest number of unique students using Core5 (week beginning November 26, 2018; 9,606 students, or 88.5% of full sample, had Core5 use), but other weeks had qualitatively similar relationships. The correlation between recommended and actual usage was similar for this sample week (Pearson $r = -0.043$, 95% CIs = -0.063, -0.023) to that seen for the aggregate results.

3.2 Event-related approach to recommendation changes

In light of these observations indicating a lack of positive alignment (Figure 2), we turned to our key question of whether student usage time in Core5 was nevertheless *responsive* to changes in personalized recommendations. Because of the complex and largely unknown (from a researcher’s perspective) context in which these personalized recommendations are implemented, we turned to an *event-related* analytic approach. This methodology allows for context-independent examinations of an event of interest by effectively contrasting responses that occur in temporal coordination with that “event” against a baseline period just before the event occurred [11].

Figure 3: Event-related analysis of usage recommendation changes. When a student’s weekly usage recommendation changes from 40 minutes (Time -1) to another duration (Time 0-2) early in a new school year, student usage tends to change in the direction of (and with magnitude correlated to) the change in recommendation. Each bold line represents the median change in actual weekly usage time across students, with all usage times in the analysis expressed as a difference from Time -1 (this is why all lines converge to 0 at Time -1). Shaded areas around each line represent 95% confidence intervals on the median generated via a bootstrap resampling procedure.

The first step in conducting this analysis is to define the event of interest - here, we focused on how each student’s first change in recommendation influenced their usage time within Core5. Note that because all students began the school year with a recommendation of 40 minutes, this event reflects a change from 40 minutes (at Time -1 in Figure 3) to one of the other four

possible usage recommendations (20, 30, 50, or 60 minutes at Time 0-2 in Figure 3). We next aligned all student data to a temporal reference frame defined by this event. In other words for each student, we defined Time -1 as their last week of program use prior to the recommendation change, Time 0 as the week when the new recommendation first appeared, and Times 1 and 2 as the next two weeks during which that same recommendation remained. Note that these weeks are ordered but are not necessarily consecutive, as students do not always use the program every week. This means it was possible for a student’s recommendation to change *again* at Time 1 or 2 if it fell in the next calendar month. To ensure that the time-course analyzed in Figure 3 reflects the response to the initial target change, we excluded 363 students (3.3%) for whom this occurred, leaving a sample of 10,488. Finally, we subtracted out each student’s actual usage time at Time -1 from all 4 time points to yield a difference metric (this is why all lines converge at 0 for Time -1).

Figure 3 shows the median event-related change in actual student usage time when a recommendation changes from 40 minutes per week at the start of the school year to another value. A two-factor ANOVA (factors of recommendation and time from 0 to 2 in Figure 3, the latter as a repeated measure) revealed significant main effects of both recommendation and time ($F_{3, 10488} = 93.564$, $p < 0.0001$, partial $\eta^2 = 0.0260$; $F_{2, 20968} = 5.71$, $p < 0.0001$, partial $\eta^2 = 0.0005$, respectively), as well as a significant interaction between time and recommendation ($F_{6, 20968} = 10.10$, $p < 0.0001$, partial $\eta^2 = 0.0030$). Repeating this statistical test with a sample that excluded outliers (353 students, or 3.4%, with a change at any time point more than 3 SDs from the mean) produced the same pattern of results. These findings clearly indicate differential responses to Core5 usage recommendations, with decreases in recommended usage (from 40 to 20 or 30 minutes per week) tending to result in decreases in program use, and increases in recommended usage (from 40 to 50 or 60 minutes per week) tending to result in increases. Interestingly, the response to a recommendation change appears to unfold in time, with students continuing to adjust usage time in the direction that their recommendation changed over the next few weeks. This finding further emphasizes the limitations of using snapshot analyses like those in Figure 2 to tease apart effects with unknown temporal dynamics.

It is notable that the median change in program use was smaller in magnitude than the recommended change, especially when one’s Core5 recommendation increased. This observation is consistent with the explanation that contextual factors specific to each student’s school and situation are weighed alongside the program’s personalized recommendations. We also found that despite the visible responses to recommendation changes (Figure 3), that average usage time for all recommendation categories tended to hover around 40 minutes per week (e.g. means in Figure 2, bottom). Such a result suggests a continued reliance on the initially recommended value of 40 minutes per week for all students (see Section 4).

3.3 Event-related approach to student fidelity of program use

As we have demonstrated, taking an event-related approach to studying learning paths in Core5 can clearly reveal differentiated student responses to personalization. While the analysis illustrated in Figure 3 represents one application of this approach to events defined directly by program-driven occurrences (changes made by Core5 at specific points in time), a key advantage of event-related

designs is their flexibility to define new events based on the nature of student actions as well [c.f. 8, 13]. To exemplify this type of approach and to gain more insight into how personalized recommendations influence students' program use, we next define new events based on whether or not a student met or exceeded their recommended usage time in a given week.

Using this definition, we can now ask whether the "event" of a student meeting or exceeding Core5's usage recommendation in a given week is associated with a lasting impact on a student's fidelity of program use, relative to weeks when that same student did not meet her Core5 usage recommendation. In other words, are these helpful recommendations that encourage students to set achievable targets, appropriately pace themselves, and use with fidelity throughout the year [19]? Because it is critical that this analysis be conducted in a within-student fashion (i.e. comparing how the same student responds to both event types), we included only students who had at least one instance of both meeting and not meeting their usage recommendation within the timeframe under study ($N=8,911$; 82.1% of full sample).

Results indicated that students more often met or exceeded their Core5 usage recommendation if they had also met or exceeded their recommendation during their prior week of program use (56.0%, vs. 50.5% when they did not meet or exceed their recommendation during the prior week; odds ratio = 1.248). We also found that while it was very likely overall for students to use Core5 in consecutive weeks, that this was even more frequent following a week of meeting than not meeting one's usage recommendation (88.0% vs. 83.6%, odds ratio = 1.438). Together, these results suggest that following personalized usage recommendations is associated with staying on track toward end of year goals and maintaining regular program use.

4. DISCUSSION

While measuring the impacts of personalized learning in school settings carries significant challenges, we demonstrate the power of an event-related analytic approach toward revealing how student behavior responds to program provided recommendations. Clearly, educators and students must make decisions about personalized recommendations within the context of their school environment and alongside myriad other considerations. The apparent lack of alignment between actual program use and Core5 recommendations (Figure 2), then, is a manifestation of these important but competing priorities. Using an event-related design, we were able to reveal that even within this complex ecosystem, students' Core5 usage time does change in a manner that directly corresponds (and is time-locked) to changes in their personalized recommendations. Furthermore, our results demonstrated that students more often stayed on track toward their end-of-year target following weeks in which they met, versus lagged behind, their suggested pace.

Although usage recommendations are visible to students in the Core5 program, given our sample's age group (K-3) we expect that teachers and school administrators are primarily responsible for monitoring Core5 usage time, responding to recommendations, and weighing program time against other educational priorities. This balancing act likely explains why students' usage time adjustments were typically smaller than was recommended (Figure 3). Together with our other findings, this pattern is consistent with program provided recommendations influencing but not determining student usage time when they are

considered alongside additional factors in each unique school context. In future work it will be interesting to investigate whether responsivity and/or alignment to usage recommendations changes with student age, perhaps reflecting increasing self-regulation and autonomy as they advance in school.

While the ability to isolate one factor of interest from within a complex, dynamical system is a key strength of an event-related approach, it is also a limitation in that it does not afford the ability to quantify influences of other factors or to provide insight as to their relative importance. From the perspective of those designing and improving personalized learning tools, however, an event-related approach is powerful for exactly that reason - it allows for isolated study of a personalized feature that is directly within the designer's control, thus facilitating improvement of the program's design and iteration on these enhancements [c.f. 14]. For example, we noted an interesting finding that even as student usage times changed in response to program provided recommendations, they seemed to remain tied to the initial, impersonal value of 40 minutes per week (e.g. Figure 2, bottom). This pattern may reflect a well-studied cognitive bias known as anchoring, which typically manifests as a continued reliance on an initially given value when making numerical judgments [24]. It may also be that educators have more flexibility to adjust student schedules early in the year than they do as school progresses. In either event, this result suggests that personalizing a student's usage recommendation earlier in the school year could yield larger impacts.

By extending our event-related approach, we found that weeks in which a student met or exceeded their personalized recommendation were more often followed by continued on-track behavior and more regular program use, which have previously been shown to be positive predictors of student performance in online courses [c.f. 7, 21]. Such an effect may stem from integration of Core5's personalized recommendations within educators' learning plans and/or with students' emerging self-regulation [1, 2, 19]. As previously described, our event-related approach limits our ability to quantify effects beyond those owing to program provided recommendations by intentionally filtering them out to isolate only a single factor. That said, these findings motivate further study of the mechanisms through which usage recommendations facilitate students' ability to stay on track for success throughout the school year.

We also note that while our approach is inspired by one developed for the analysis of brain imaging data, it differs in important ways. First and foremost, event-related designs in brain imaging research are typically used in the context of randomized studies, where an experimenter controls many aspects of the timing and context of "events" (although note that the ability to flexibly define events post-hoc is a key methodological advantage, c.f. 8). In contrast, Core5 students are assigned usage recommendations based on their pace through content material and the amount they have left to finish that year. By definition, then, students who are farther behind in class will tend to receive higher Core5 usage recommendations. Although the analyses we present highlight within-student usage changes in response to time-locked events, it is important to note that the groups of students at each recommendation level (e.g. at Times 0-2 in Figure 3) likely differ in other key ways. For example, we may speculate that one reason why usage time increases were typically of smaller magnitude than usage time decreases (Figure 3) could be that students who are farther behind tend to receive offline

interventions at school rather than additional time in the online program.

Analytic applications in the field of brain imaging also suggest extensions of this work that could yield continued insights into the impact of personalization in learning. For example, once well characterized, event-related time courses serve as a template for identifying structural brain regions with particular functional properties [8, 13]. Analogously, having defined the typical time course of how student usage responds to recommendation changes (Figure 3), we could now use these expected functions as regressors to identify schools where recommendations are or are not strongly implemented. This in turn could help guide vendors to better help schools resolve issues and successfully implement digital learning tools. It could also motivate additional research studies that compare student outcomes in school contexts where personalized recommendations either were or were not implemented with fidelity. Such investigations will yield a deeper understanding of the value of personalized recommendations within schools, and in turn provide examples that enable educators to operationalize personalization in their classrooms.

ABSTRACT

Intelligent Tutoring Systems (ITSs) have been developed to provide students with personalized learning experiences by adaptively generating learning paths optimized for each individual. Within the vast scope of ITS, score prediction stands out as an area of study that enables students to construct individually realistic goals based on their current position. Via the expected score provided by the ITS, a student can instantaneously compare one's expected score to one's actual score, which directly corresponds to the reliability that the ITS can instill. In other words, refining the precision of predicted scores strictly correlates to the level of confidence that a student may have with an ITS, which will evidently ensue improved student engagement. However, previous studies have solely concentrated on improving the performance of a prediction model, largely lacking focus on the benefits generated by its practical application. In this paper, we demonstrate that the accuracy of the score prediction model deployed in a real-world setting significantly impacts user engagement by providing empirical evidence. To that end, we apply a state-of-the-art deep attentive neural network-based score prediction model to *Santa*, a multi-platform English ITS with approximately 780K users in South Korea that exclusively focuses on the TOEIC (Test of English for International Communications) standardized examinations. We run a controlled A/B test on the ITS with two models, respectively based on collaborative filtering and deep attentive neural networks, to verify whether the more accurate model engenders any student engagement. The results conclude that the attentive model not only induces high student morale (e.g. higher diagnostic test completion ratio, number of questions answered, etc.) but also encourages active engagement (e.g. higher purchase rate, improved total profit, etc.) on *Santa*.

Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 743 - 748

1. INTRODUCTION

The significance that standardized examinations (e.g. SAT and TOEIC) currently hold is to provide an objective criteria in which each individual's academic performance is measured. Accordingly, Intelligent Tutoring Systems (ITSs), which generate optimized learning paths for each student, often include functions such as estimating expected performance on standardized examinations. In this regard, measuring the expected academic performance of a student has become an interesting area of study in Artificial Intelligence in Education (AIED). These studies focus on modelling a student's understanding of a target subject based on their learning activities. For instance, Matrix Factorization (MF) [10, 22, 16, 17, 23, 7, 25, 24] is a prevalent method used for grade prediction, in which the latent vectors of students and courses are learned by factorizing a student-grade matrix into two low-rank matrices. Markov and semi-Markov models are also some other popular approaches for grade prediction [11, 7, 23]. With the advances in deep learning, neural network based models with deeper hidden layers, such as Multi-Layer Perceptron, Recurrent Neural Networks and Convolutional Neural Networks, were introduced to predict student's academic performance [21, 9, 11, 8]. In [3], the Transformer-based [29] bidirectional encoder model was first pre-trained to predict masked assessments and then fine-tuned to predict exam score, resulting in a state-of-the-art score prediction model. Although precision of academic performance prediction is significant as it is directly associated to a reliability of an ITS, previous studies have mainly focused on improving the accuracy of the prediction, leaving discussion about the benefits of precise prediction on student engagement fairly opaque.

In this paper, we direct our attention towards the correlation between the precision of score prediction and student engagement. Our study starts by hypothesizing that students will show higher level of engagement if they experience a more precise score prediction while interacting with ITS. We empirically verify our hypothesis on *Santa*, a multi-platform English ITS with approximately 780K users in South Korea that exclusively focuses on the TOEIC (Test of English for International Communications) Listening and Reading Test Preparation. In the experimental studies, we run a controlled A/B test with two score prediction models that differ in accuracy, which are respectively based on collab-

*Equal contribution.

orative filtering with Mean Absolute Error (MAE) of 78.9 and deep attentive neural networks with MAE of 49.8. The results show that the superior performing, deep attentive neural network based score prediction model induces more student engagement. These benefits range from ones that are derived from learning behavior (e.g. preliminary test completion ratio, membership rates, the average number of questions a student answered after the diagnostic test) to more active engagement (e.g. purchase rate, average revenue per user, and total profit). To the best of our knowledge, this is the first work studying the benefits of accurate score prediction of ITS on student engagement.

2. RELATED WORKS

The related works of this study can be grouped into two categories: academic performance prediction and student engagement.

2.1 Academic Performance Prediction

Predicting a student's academic performance is a significant aspect in solving the problems within AIED. A successful prediction model can be used to recommend appropriate courses, provide interventions for at-risk students, and optimally allocate learning materials. Extensive work has been conducted on performance prediction, exploring a wide range of methodologies from simple regressions to deep learning.

The most widely used methodology in grade prediction is low rank Matrix Factorization (MF) [10, 22, 16, 17, 23, 7, 25, 24]. Low rank MF assumes that there is a low-dimensional latent space containing features that can effectively represent both students and the academic tasks students will be graded on. These features can be interpreted as representations of a student's knowledge. We find these features by decomposing a student-grade matrix into a product of two low-rank matrices. The authors of [22] show that the MF-based model outperforms other course/student-specific regression models. [16] improved the model by assuming that different courses share a common latent feature space, since the totality of a student's knowledge should not change based on the courses they are taking.

Markov and semi-Markov models are another popular set of models for grade prediction [11, 7, 23]. These models capture the dynamic evolution of a student's learning status and leverage it to effectively predict outcomes. [7] develops course-specific hidden Markov and semi-Markov models for grade prediction. [11] models student behavior in MOOCs by using Hidden Markov Models (HMMs) and Multinomial Mixture Models (MMMs) to cluster sequences of student actions. The study applies an LSTM model to predict the students' final grades. Markov models are also used to estimate a student's performance on educational games [28] or to predict student retention in MOOCs [1].

[21, 9, 11, 8] introduce deep-learning based prediction models. The authors of [9] introduce two types of Bayesian deep learning models for grade prediction using Multi-Layer Perceptron and LSTM architectures. Their results show that their model outperforms several baseline models (including MF-based models and course-specific regression models) in detecting at-risk students. The authors of [3] propose As-

essment Modeling (AM), a pre-training method applicable to general ITSs. In AM, a model is first pre-trained to predict several assessments of a student automatically made by ITS during one's learning process. Their results show that a Transformer [29] based neural network model with AM improves model accuracy compared to the same network with other state-of-the-art pre-training methods (such as BERT [5] based word embedding and QuesNet [31] question embedding) on exam score prediction and review correctness prediction.

2.2 Student Engagement

Student engagement is also an actively studied topic in the field of AIED. Several works have analyzed student engagement patterns to figure out which factors vastly impact engagement. [30] studied how people use digital textbooks and compare engagement patterns among high school students, college students, and online website viewers. [18] investigated student engagement in an online learning system which outperformed a traditional classroom on key indicators of engagement, such as time on-task, engaged concentration, and boredom. [26] found correlations between semantic features of mathematics problems and indicators of engagement. [14] discriminated behavioral engagement and cognitive engagement, and argued that most of students who were behaviorally engaged were not cognitively engaged.

Another line of student engagement research focused on predicting engagement level. [20] proposed a two-phased approach for automatic engagement detection, which utilized contextual logs and appearance information to infer behavioral engagement. [19] investigated the relationship between engagement and performance. Firstly, this work analyzed log traces for each learner to calculate engagement indicators that represent learner's engagement level. Based on the quantified engagement indicators, prediction on the learner's performance were attempted.

Enrollment is a sign of strong engagement since it involves determination that a student must invest to take a certain course. Accordingly, predicting and promoting enrollment is highly relevant to student engagement research. [6] proposed a novel extension of Factorization Machines to infer students' course enrollment information from incomplete data. [2] presented a course enrollment recommender system which recommended selective and optional courses based on students' skills, knowledge and interests. [27] identified factors that affect the likelihood of enrolling. This work analyzed the enrollment predictability of such factors using logistic regression, support vector machines, and semi-supervised probability methods.

With the development of Massive Open Online Courses (MOOCs), several works studied student engagement in a MOOCs environment. [12] proposed a recommender which provides each student with an individual list of contacts based on their own profile and activities to foster their engagement in MOOCs. [15] investigated the relationship between students' self-evaluation of their previous knowledge and students' engagement behaviors in MOOCs through a polytomous item response theory model.

3. SCORE PREDICTION MODELS

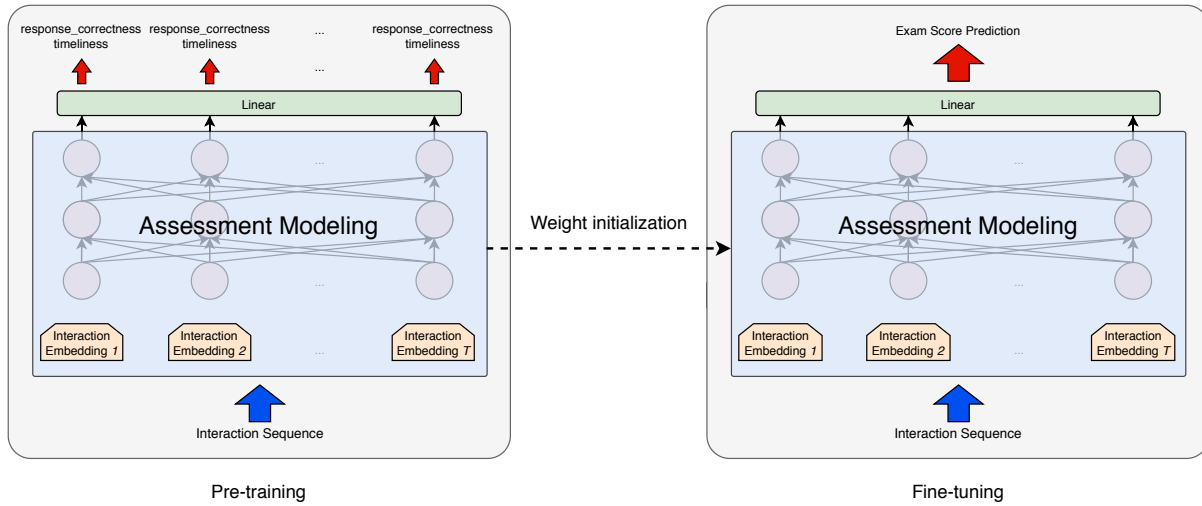

Figure 1: Pre-training/fine-tuning scheme of Assessment Modeling for score prediction. First, a model is pre-trained to predict two assessments: response correctness and timeliness. After pre-training, the last layer of the model is replaced with a layer with randomly initialized weights and appropriate dimension for score prediction. The parameters in the model are fine-tuned to predict exam scores.

Our studies are based on comparing the two approaches for score prediction: a collaborative filtering based approach and Assessment Modeling. The following subsections briefly cover each approach. More detailed descriptions can be found in [13] and [3].

3.1 Collaborative Filtering based Approach

There are two phases in the Collaborative Filtering (CF)-based score prediction approach. First, the CF-based model developed in [13] estimates the probability that a student responds correctly to each potential question. In this model, each user or question is represented as a k -dimensional latent vector, where k is the number of hidden concepts. For instance, if there are n users with m questions, we have user vectors L_1, L_2, \dots, L_n and question vectors R_1, R_2, \dots, R_m each with dimension k . The knowledge level of user i understanding question j is represented as $X_{ij} = L_i \cdot R_j$. Accordingly, the probability of user i getting question j correct is modeled as

$$\phi(X_{ij}) = \phi_a + \frac{1 - \phi_a}{1 + e^{-\phi_c(X_{ij} - \phi_b)}},$$

where ϕ_a , ϕ_b , and ϕ_c are parameters appropriately set, independently of questions or users. The learning algorithm then finds the maximum likelihood estimator by minimizing the negative of log-likelihood of observed user-question entries with Frobenius norm regularizer terms through the projected stochastic gradient descent.

Given the response correctness probabilities calculated from the CF-based model, scores for Listening Comprehension (LC) and Reading Comprehension (RC) are calculated through the following quadratic equations

$$\begin{aligned} score_{LC} &= \theta_2 x_{LC}^2 + \theta_1 x_{LC} + \theta_0 \\ score_{RC} &= \theta_5 x_{RC}^2 + \theta_4 x_{RC} + \theta_3, \end{aligned}$$

where x_{LC} and x_{RC} are each the average of predicted response correctness probability of potential questions in LC and RC, and θ s are properly set parameters. The final score is the sum of $score_{LC}$ and $score_{RC}$.

3.2 Assessment Modeling

[3] introduced Assessment Modeling (AM), a fundamental pre-training method for general class of ITSs. The motivation behind the works of AM is to deal with label-scarce problems in AIED. Score prediction is a typical example of such label-scarce educational problems since standardized exam scores are not obtainable within ITS. Collecting the exam scores involves student action taken outside ITS. The approach proposed in [3] is based on a pre-training/fine-tuning paradigm. In the pre-training phase, the Transformer-based [29] bidirectional encoder model is trained to predict randomly masked assessments, which are interactive educational features available in ITS. Examples of these assessments include response correctness (whether a student provides a correct response to a given question) and timeliness (Whether a student responds to each question within the time limit specified by domain experts). In the fine-tuning phase, the last layer of the pre-trained model is replaced with a randomly initialized layer with an appropriate dimension for a specific downstream task. Afterwards, the parameters in the model are updated to predict labels in the downstream task. In the experimental studies conducted on EdNet [4], AM outperformed pre-training methods that learn the contents of learning materials in several downstream tasks including score prediction. See Figure 1 for graphical description of AM.

4. EXPERIMENTS

4.1 Santa service

Santa is a multi-platform English ITS with approximately 780K users in South Korea that exclusively focuses on the

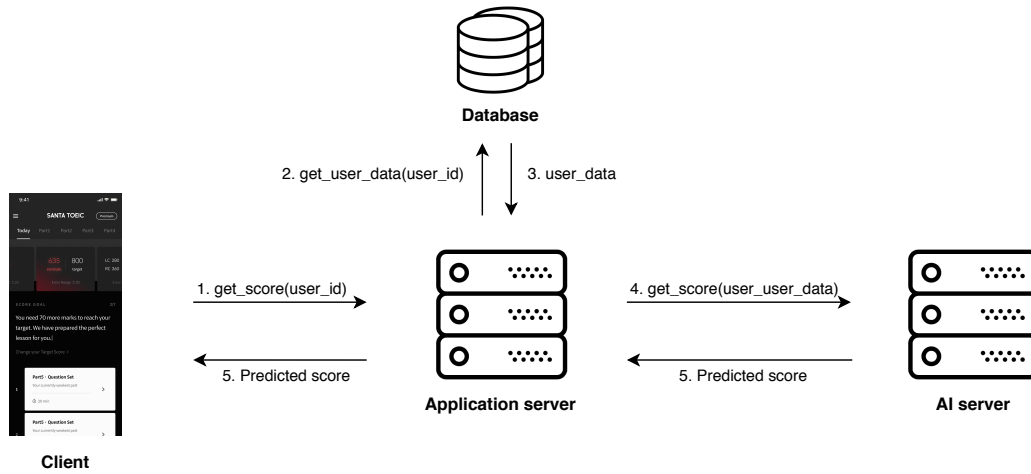

Figure 2: The flow of score prediction.

TOEIC (Test of English for International Communications) standardized examinations. TOEIC is an English proficiency test that consists of two timed sections (listening and reading) each with 100 questions that adds up to a combined total score between 0 to 990. Santa utilizes several AI techniques to optimize the preparation process of the TOEIC examination for students. When the application is first initiated, a preliminary placement test with 7 to 11 problems is given to diagnose the student’s current state and predict their expected score in real-time. After the diagnostic test, a user response prediction model is used to dynamically suggest problems which corresponds to the student’s current position within the TOEIC ladder. The prediction model is calculated by computing a user’s overall correctness rate, eliminating problems that students have answered correctly with high probability and then selecting the best possible content based on expert heuristics. Based on the user’s previous data, the predicted scores can be provided in various forms throughout the service, as shown in Figure 3. Figure 2 shows the flow of score prediction.

Figure 3: Various representations of predicted scores within the application.

4.2 Performance of Score Prediction Model

Santa has previously used a CF-based model for score prediction which has recently been replaced with a deep attentive model. To train the model, we aggregate the real TOEIC scores reported by users of Santa. Santa offered to reward to the users who have reported their score and was able to obtain a total of 2,594 score reports for 6 months. The data is then divided into a training set (1,302 users, 1815 labels), validation set (244 users, 260 labels), and a test set (466 users, 519 labels). We use EdNet as pre-training task data and the student sequence data as the label (TOEIC score). Table 4.2 shows the MAE (Mean Absolute Error) of the two models for the test set.

	CF	Deep Attentive model
MAE	78.91	49.84

Table 1: MAE of collaborative filtering and attentive model

4.3 A/B test setup

From February 24th to April 2nd, we conducted an A/B test by randomly administering two different score prediction algorithms to the application users: one based on a collaborative-filtering algorithm and another one based on deep-learning. 50,451 students were allocated to the collaborative filtering algorithm and 17,019 students were provided a deep-learning algorithm. We analyzed each student’s response and action (such as time of registration, question response time, purchase rate, etc.) to spot any noteworthy statistics that can validate our experiment.

4.4 Experimental Results

In this section, we discuss how a high quality of the predicted scores can significantly impact student morale.

4.4.1 Student Motivation

Our first test statistic is the preliminary test completion ratio. The completion rate of the initial placement test is a crucial indicator that could represent a student’s motivation,

Figure 4: Comparison of the number of questions solved per day between the users of the A/B test.

as only students who are willing to learn will try to finish their diagnostic test. For each question a student answers in SANTA, a predicted score that is updated in real-time is projected on the top left corner. This allows for the user to immediately check the quality of the expected score, thus strengthening the trust that the user may have with the application. A/B test results show that the deep attentive model has a higher completion rate of 64.93% than the CF-model with 65.90%.

Next, we look at changes in membership rates. A membership rate of an application in a sense signifies greater magnitude of student motivation than the completion rate as it directly indicates the determination of a user who wishes to use the application. Out of a total of 67,470 users that have used Santa during the A/B test period, 44,297 users finished their diagnostic tests and 28,065 users have registered to sign up with the application. The A/B test shows that the deep attentive model has a registration rate of 43.13% while the CF-based model has 44.55%.

The average number of questions a user answered after the diagnostic test is also significant proof of a student's educational drive. The A/B test results show that with a deep attentive model a student solved an average of 22.73 questions, while with a CF-based model the user only solved 20.03. Figure 4 shows the comparison of the number of questions answered per day between the users of the A/B test. The x-axis represents the date and the y-axis represents the gap between average number of questions answered in a deep attentive model and a CF-based model. If the gap is positive, the former model has on average more questions solved, and vice versa. We can observe that more questions from the deep attentive model were solved mostly throughout the A/B test time period.

	CF	Deep Attentive model
Completion rate (%)	64.93	65.90
Registration rate (%)	43.13	44.55
# of solved questions	20.03	22.73

Table 2: Experimental results of student motivation

4.4.2 Active Student Engagement

In this section, we demonstrate active student engagement based on different score prediction models via taking a look at the financial benefits the models bring. Monetary profits are an essential factor in evaluating a service, since it is

an important indicator of user engagement as a high level of user engagement directly results in financial success. We measure business impact with 3 metrics : purchase rate, Average Revenue Per User (ARPU), and total profit. In this context, purchase rate is defined as the number of users that decided to purchase full access to the app during the A/B test period. The test results show that the purchase rate for the deep attentive model was 2.73% while the CF-based model had a 2.37% rate, showing a 15.19% increase for the deep attentive model. For ARPU, the deep attentive model averaged \$3.23 whilst a CF-based model averaged \$2.83. Total profit during testing period also yielded \$162,933.88 for the former while it only gathered \$142,949.55 for the latter (since the two models had different parameters, these values were normalized based on the ratio of the model parameters). Comparing these 3 metrics, we conclude that the model with higher accuracy in the deep attentive model shows better results as well.

	CF	Deep Attentive model
Conversion rate (%)	2.37	2.73
ARPU (\$)	2.83	3.23
Total profit (\$)	142,949.55	162,933.88

Table 3: Experimental results of student engagement

5. CONCLUSIONS

Recent developments in ITS have enabled customized education by suggesting optimal strategies for individual students to approach studying. SANTA has also assisted its users to better prepare for the TOEIC English fluency standardized examinations by utilizing various learning techniques. Recently, SANTA has shifted from a collaborative-filtering model to a deep attentive model that has proved to be an upgrade over the former. To inquire about the benefits of using a fastidious model, this paper conducts various experiments and investigates their results. Analyzing the results of various experiments leads us to believe that deep attentive model entails a higher level of student motivation and engagement. Therefore, we claim that a more accurate model, in this case, the deep attentive model, could induce improved student engagement.

ABSTRACT

With the development of personalized learning in technological platforms, more data and information are given to instructors on what contents are appropriate for a learner's next step, with an aim of helping them support their students in navigating an optimized learning path that can promote an enhanced learning outcome. In this study, we collected data from an online learning platform, Learnta[®] TAD, which allows teachers to distribute tasks based on system recommendations. The recommendations are directed by the system's knowledge graph algorithm, determining whether the student is ready to learn the task (i.e. the task is within the student's Zone of Proximal Development), whether the student is not yet ready to learn the task, or whether the student has already mastered the task. We used the acquired data to investigate whether giving content in each of these groups results in different learning outcomes. Statistical methods such as subgroup analysis, Fisher's exact test, and logistic regression are conducted to address the proposed topic. Replicating a prior, smaller-scale study, our findings suggest that the student gains more mastery when assigned Ready-to-Learn tasks than when assigned Unready-to-Learn tasks, across Math and English, more and less successful students, and in-class and homework. Moreover, students who are given already mastered tasks perform better than those who are given Ready-to-Learn and Unready-to-Learn tasks across all groups.

1. INTRODUCTION

Increasingly, teachers' decisions are driven by data [3], with increasing data becoming available from online learning environments [9]. Using reports from online learning systems, educators are able to track and evaluate each student's learning based on data [1]. However, even though data are given to teachers by these systems, instructors are still impeded by having insufficient knowledge about how to use the data [7]. In other words, teachers still have difficulties in using data effectively to decide what students need to learn next, to maximize learning outcomes and expedite the learning process.

This problem is exacerbated in online learning systems that give relatively more agency to teachers in choosing which content their students will work with. Although such systems are easier to integrate with existing pedagogical practices, they raise questions as to whether teachers will assign the best possible content. We can consider this decision in terms of whether a teacher selects content that falls within a learner's zone of proximal development (ZPD) [8]. A task within a learner's ZPD is one that he or she can succeed in, but only with external support or scaffolding. Tasks that a learner can succeed in without support, and tasks that a learner cannot succeed in even with support, fall outside of the learner's ZPD. Although the ZPD has been a popular concept in the educational literature for decades, only limited attention has been paid to ZPD in educational data mining and related communities [4].

However, recent research has found evidence that Vygotsky's concept of the ZPD can be beneficial to the design of adaptive learning systems [10]. In that work, Zou and colleagues investigated whether teachers make good instructional decisions based on student performance data. They compared "Ready-to-Learn" (RtL) content inside the ZPD to content that students were "Unready-to-Learn" (UtL), using automated assessments of student progress through a curriculum based on a knowledge graph.

We replicate and build on this work with a larger student sample, assessing whether a task is RtL for a specific student using the prerequisite structure within a knowledge graph. Our hypothesis is that, like in [10], students will gain more mastery (successfully complete more objectives within the

system) if they are assigned RtL tasks instead of UtL tasks. We also investigate whether the findings in [10] are robust to whether the student is completing tasks as homework as opposed to in class. We hypothesize that students working on content in class will gain more mastery than students completing tasks as homework, due to the availability of greater learning support and scaffolding in an in-class context [6]. We also investigate whether the findings in [10] are robust to the general level of success of the student. If some students are simply faster or better learners than others in a domain (e.g. [2]), then they may be able to perform better even when given UtL. However, one could also argue that if the knowledge graph is correct, then all students should have similar (poorer) outcomes for UtL content, since regardless of their general ability they lack the building blocks to acquire the content they are given. Finally, we investigate whether the results in [10] are robust across two different learning subjects, English and Mathematics.

2. THE ONLINE LEARNING PLATFORM

The system used in this study is a learning platform for K-12 students in China, called Learnta[®] TAD, developed by Learnta Inc.. Learnta[®] TAD, an acronym of “Teacher + Artificial Intelligence + Data”, is a system which gives teachers data on student learning progress and makes recommendations on optimal learning path using AI algorithms, and then allows teachers to decide which content students should work on. Learnta[®] TAD is primarily used in blended learning, where teachers give students face-to-face instructions in classroom.

Figure 1: Teacher’s Interface of Learnta[®] TAD system

In TAD, teachers assign learning tasks that contain several target skills to the students. The system infers each student’s mastery of each skill using Bayesian Knowledge Tracing (BKT) (Corbett & Anderson, 1995) by predicting the student’s latent knowledge state according to the student’s correctness on questions related to the skills. Learnta’s directed knowledge graph maps content to a prerequisite structure, representing which prerequisite content is necessary to know to learn a particular piece of content. Based on the mastery of the student and the prerequisite structure of each

skill, Learnta[®] TAD recommends RtL contents for teachers to instruct. More specifically, content is considered RtL if the student has mastered all the prerequisites of that skill; UtL indicates that the student is missing one or more of a skill’s prerequisites. Whether or not the teachers choose to follow the recommendations, the system collects data on the students’ performance and learning outcomes. Teachers can assign material that is RtL, UtL, or even Already Mastered (AM).

Figure 2: Teacher using Learnta[®] TAD in classroom

3. DATA COLLECTION

To investigate our research questions around ZPD status and students’ learning outcomes, we collected data from 7913 middle school and elementary school students who studied 250,783 task cards (one task card contains several skills) in Learnta[®] TAD, during 2019.

In the context of both English and Math, we categorized students into different levels based on their earlier assessment test performance: 1) Excellent students; 2) Normal students; 3) Struggling students. Excellent students are those who mastered at least 80% of the skills in the assessment, according to Bayesian Knowledge Tracing. Normal students are those who mastered at least 60% but less than 80% of the skills in the assessment. Struggling students are those who mastered less than 60% of the skills in the assessment. The proportion of these three student categories is 32.39%, 53.78% and 13.83%, respectively.

In addition to that, we compare the use of the system in a classroom setting to its use as homework. In-class, students complete the assigned tasks under the supervision of their teachers during a class session. Within the homework context, students are expected to complete their tasks at home. The percentage of these two scenarios are 57.5 % and 42.5 %, respectively.

4. STATISTICAL ANALYSIS

We compare the learning outcomes of teachers’ decisions of what skills the student should work on. The analyses are conducted on two topics - Math and English - separately. The outcome of interest is whether the student mastered the skill according to BKT. The percentage of skills that are mastered are tabulated for each type of teaching decisions: RtL, UtL, and AM.

In addition to descriptive statistics, we conduct Fisher’s exact test to assess the association between instructional decisions and student mastery. Our hypothesis is that students are more likely to master RtL skills than UtL skills.

In addition, a logistic regression model is used, with learning outcome as the independent variable, and teacher’s decision, student’s level, and whether learning occurs in a classroom as predictors.

P values are calculated in R version 3.6.3 using the `fisher.test()` function for Fisher’s exact test and the `glm()` function for logistic regression.

5. RESULTS

For the tasks in Math, the completion rates were 76.5%, 70%, and 65%, respectively, for the excellent, normal and struggling students. The completion rates were 79%, 72%, and 66.5% in English. Those findings indicate that the students’ completion rates vary depending on overall student success, $\chi^2(df = 2, N = 93874) = 650.29, p < 0.001$ for Math and $\chi^2(df = 2, N = 146127) = 1465.87, p < 0.001$ for English.

The completion rates for in-class tasks were 75.7% for Math and 74.7% for English, and for homework tasks the completion rate were 65.3% for Math, and 70.3% for English (see Figures 3 and 4). Fisher’s exact tests show the in-class tasks were more likely to be completed than the homework tasks for both Math ($p < 0.001$) and English ($p < 0.001$).

Figure 3: Completion Rate in Math

Figure 4: Completion Rate in English

The mastery rates by subject and student success level are presented in Figures 5 and 6. We conducted the Fisher’s

exact tests and it demonstrated that the excellent students had a better performance in terms of mastery rates compared to the normal students (Math, 68.6% vs. 52.1%, $p < 0.001$; English, 63.6% vs. 54.7%, $p < 0.001$). The mastery rates were much lower for the struggling students (Math, 36.9%, $p < 0.001$; English, 11.9%, $p < 0.001$).

Figure 5: Mastery in Math subject

Figure 6: Mastery in English subject

Figures 7 and 8 show that the average mastery rate of RtL tasks was significantly higher than that of UtL tasks, $p < 0.001$ for each of the three student success levels in each subject, using Fisher’s exact test.

The logistic regression provided further evidence that ZPD status was associated with students’ learning outcome ($F(2, 38891) = 119.85, p < 0.001$ for Math and $F(2, 1996) = 30.74, p < 0.001$ for English), with adjustment for task type and student success levels. In particular, a RtL task was more likely to be mastered than a UtL task (Math, $OR = 1.710, p < 0.001$; English, $OR = 7.709, p < 0.001$), but was less likely to be mastered than an AM task ($OR = 0.241, p < 0.001$ for Math and $OR = 0.185, p < 0.001$ for English). Moreover, the logistic regression also suggested that students were more likely to master a math skill in class compared to homework ($t(38891) = 2.676, p = 0.007$), while the mastery rates of English skills were similar between the two settings ($t(1996) = 0.706, p = 0.480$).

Moreover, interaction terms were added to the logistic regression model in order to test the hypothesis that the relationship between ZPD status and learning outcome was

Figure 7: ZPD v.s Mastery in Math subject

Figure 8: ZPD v.s Mastery in English subject

different for students with various success levels (i.e., excellent, normal, struggling). It turned out that, within the subject Math, the improvement on learning outcome associated with RtL status were comparable among the three student groups ($F(2, 30664) = 4.374$, $p = 0.126$), which was consistent with the observation that three lines corresponding to different success levels are almost parallel in Figure 7. Within the English subject, however, the analysis results indicated an interaction effect between RtL status and student success levels ($F(2, 1587) = 8.763$, $p < 0.001$): the excellent students tended to benefit less from being assigned a RtL task instead of a UtL task than either normal students ($p < 0.001$) or struggling students ($p = 0.002$). The conclusion with respect to AM tasks was less clear because there were fewer struggling students to begin with.

Lastly, we did not find statistical evidence for there being an interaction effect between ZPD status and whether the system was used in class or as homework ($t(38891) = -0.282$, $p = 0.778$ for Math and $t(1996) = 1.859$, $p = 0.063$ for English). This suggests that it is likely important to assign RtL content to students regardless of which setting the system is used in, although it may be warranted to continue investigating whether RtL content has more benefit for students studying English in class, based on the marginally significant

p value in that analysis.

6. DISCUSSION & CONCLUSION

In the light of these results, we can re-consider our original research questions. We hypothesized that, as in [10], students would master more tasks if presented with content thought to be in their ZPD (Ready-to-Learn content) than content outside of their current ZPD (Unready-to-Learn content). Our findings are compatible with this hypothesis, providing a replication of the earlier work in [10]. We also find that this pattern replicates across two domains, Math and English.

Our second hypothesis was that students would have higher mastery rates in class than when completing homework; this hypothesis was upheld for math subject but not upheld for English subject. Our finding is that students were slightly more likely to master a math skill in class than as a homework, while the mastery rates of English skills was comparable between the two contexts. This finding may suggest that the learning support within the platform was more effective than anticipated; alternatively, it may be that the instructors using the platform in their classes have not yet learned effective pedagogies for teaching students using this type of technology. Effective teaching in these contexts involves different pedagogies than are necessary within traditional classrooms [6], and there is increasing evidence that many teachers do not adopt these pedagogies until their second year of teaching with a new technology [5].

Our third research question asked whether generally more successful students would perform better than other students, even for content seemingly outside their zone of proximal development. In line with past work by Liu and Koedinger (2015) [2], it seemed that these more successful students were more able to succeed, even on this content that was anticipated to be highly difficult. However, they still performed more poorly on this content than on content thought to be in their ZPD.

Overall, these results suggest that assigning content with regards to a student's zone of proximal development can lead to a higher probability of the student mastering the content they are given. This result, a replication of [10], appears to hold in more than one learning domain. However, there are several important areas of future work before this finding can truly be held to be robust. First, this finding should be replicated in a broader range of contexts – other learning systems, other learning domains, and a wider range of learner populations and countries. Second, it is probably warranted to look at other definitions of the ZPD to refine this finding – is there an optimal degree of prior mastery for assignment of a student within the knowledge graph? Would alternate definitions of ZPD, such as seen in Murray and Arroyo's work (2002)[4], be equally or more effective? Does this type of finding also hold within systems where content is not consolidated into skills but is more factual in nature? By learning the answer to these questions, we can improve the effectiveness of adaptive learning systems more broadly, while helping to better operationalize and understand one of the classic theories in the history of thought on education.

ABSTRACT

The communication presents a doctoral research currently underway in the context of adult e-education. It's interested in spontaneous mutual helping behaviors between learners engaged in fully online learning. It aims to identify the nature of this mutual help and to examine the influence of the feeling of social belonging on this mutual aid.

In order to give an overview of this thesis work, we were inspired by research carried out on mutual aid behaviors, prosocial behaviors and the feeling of social belonging. The basic psychological needs theory has also provided theoretical support for this research.

For the empirical study, we favored a comprehensive approach integrating a mixed methodology involving various sources of data collection and different methods of analyzing this data: correlation analysis on quantitative data from a survey questionnaire, lexicometric and thematic analysis on qualitative data from interviews and analysis of traces of mutual help on the platform's forums. The results of these analysis shed light on the perception of the feeling of social belonging and its role in helping behavior.

Keywords

Mutual help, feeling of belonging, distance learning.

1. INTRODUCTION

With the evolution of online communication tools, the learner engaged in an e-learning system has multiple possibilities to interact with his teachers, tutors or peers as part of his training. These interactions make it possible to create a socio-emotional climate favorable to transactions between learners (confrontation of their points of view, mutual adjustments,

negotiations) and to break the isolation [1]. The development of interactions between all actors of a device can be realized only if there is commitment between each other. In a context of adult e-education, engaging in a training project and persevering depends on several factors: individual psychological factors influenced by the social environment and the relationship with others, social experience, favorable or unfavorable dispositions training, personal and professional projects [2].]. It is in this particular context of adult education and elearning that this search is registered. It aims to describe spontaneous helping behaviors between learners i.e. helping behaviors initiated by the caregiver without having been invited [3] and to examine the feeling of belonging effect on these behaviors. In this perspective, our research aims to answer the following questions:

How do learners help each other? Are their mutual help behaviors linked to a sense of social belonging?

First, we are going to describe the theoretical framework. We will give the definition of our research dimensions, then we will detail the research methodology. Finally, we will present the results and the first conclusions.

2. THEORETICAL FRAMEWORK

2.1 Mutual help

Mutual help has been the subject of several researches in various fields and on different groups of people. Peer support experiences in primary and general secondary education, described either as "tutoring" or as "monitoring", cover identical practices. These are always mediation situations where a learner helps another learner in his academic, methodological learning and in the organization of his personal work [4]. In the context of e-learning, a helping relationship refers to tutoring where the help consists of psychological support which adopts empathy, active listening and non-judgment [5]. In their review of the literature on the learners e-learning experience, Dieumegard and Durand have shown that in several systems, learners tend to move away from institutionalized exchange spaces to help each other [6]. In addition, other research has also shown the emergence of mutual help networks at a given time in e-learning [7]. The analysis made on the exchanges between learners on the forums revealed, among other things, that these networks could consolidate the learning

Dalila Bebbouchi "Mutual spontaneous aid between students in distance learning and the role of the feeling of social belonging to a training group" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 754 - 757

process, recreate a space-time of meeting in order to reduce the "distance" and to overcome technical problems. Furthermore, in the context of work and organizations, helping behavior has been identified as an important form of organizational citizenship [8]. Paillé defines mutual help as a helping behavior which "consists for a person in providing assistance to a colleague to enable him to solve a problem or to avoid the emergence of difficulties encountered in the performance of his work" [9]. This helping includes four dimensions: altruism which is a voluntary actions that help another person with a work problem, peacemaking defines the actions that help to prevent, resolve or mitigate unconstructive interpersonal conflict; cheerleading which means the words and gestures of encouragement and reinforcement of coworkers' accomplishments and professional development and finally courtesy which involves helping others by taking steps to prevent the creation of problems for coworkers [8].

2.2 The feeling of social belonging

Several names for the concept of the feeling of social belonging are used in an undifferentiated way in the research work [10, 11, 1] such as "Affiliation", "relatedness", "Connectedness", "belongingness". This feeling cannot be formed individually [10], it can only exist if the individual is accepted and recognized by the other or more precisely by the members of the group with whom he wants to be and wishes to share his values [12].

The feeling of social belonging is expressed by two sub-dimensions [11]: the feeling of intimacy and proximity between two or more people expressed by the fact of being attached, united or friend with the other, the second sub-dimension refers to the feeling of acceptance which expresses the fact of being accepted, understood, valued, listened to or even in trust with the other. Acceptance by others leads to a variety of positive emotions (happiness, delight, well-being, calm) while being rejected, excluded or ignored leads to powerful negative feelings such as depression, grief, jealousy and loneliness. The emotions that people experience, which are both positive and negative, are linked to the feeling of belonging [13]. It should be noted that the feeling of social belonging is strongly linked to the need to belong. Indeed, the first is centered on others and the second is linked to the image given to others [14]. This need according to Deci and Ryan is part of the fundamental psychological needs inherent in human nature [15].

3. METHODOLOGY

This research is based on a comprehensive approach. It integrates several sources of data collection. Also, it takes into account different levels of analysis to obtain a richer understanding of the feeling of social belonging and its role in helping behavior. The chosen field of study concerns two promotions of the online training Master 2 "Multimedia Pedagogical Engineering" (IPM). This master is provided by the Department of Education Sciences and Adult Education (SEFA) of Lille University. The first promotion was at the beginning of the course and the second at the end of the course. The majority of learners are adults continuing their studies. Teaching is done through an e-learning platform ACCEL (Collaborative Learning and Online Community). ACCEL is an online learning platform for group animation based on organized asynchronous exchanges enriched with documents [16].

Data collection was carried out in three stages: a first stage aimed at examining the field through the administration of a survey questionnaire sent to 114 learners distributed as follows: 62 learners at the end of the course and 52 learners at the beginning of the course. The questionnaire was designed on the basis of psychometric scales validated theoretically and empirically: ESAS scale [11] which measures the feeling of social belonging and the mutual helping scale [8] which measures the helping behavior as defined by Podsakoff and al. [9].

The second data collection comes from semi directed interviews conducted by VoIP with a panel of 20 volunteer students: 12 students at the end of course and 08 learners at the beginning of course. The interview guide was designed considering the indicators of the feeling of social belonging and mutual help.

Finally, third collection of data was taken from the traces of mutual help between learners on the platform's forums, 1400 contributions were analyzed.

4. RESULTS AND ANALYSIS

The correlation analysis conducted on the quantitative results reveals that there are no significant links between mutual help and the feeling of social belonging at the beginning of the course (Table 1). There is a negative correlation between the indicators of mutual help and the feeling of intimacy. On the other hand, for respondents from the promotion at the end of the course, the analysis shows that there is a significant link between the feeling of intimacy (indicator of the feeling of social belonging) and peacemaking (indicator of mutual help) (table 2)

Table 1: Correlations analysis at the start of the course

	Acceptance	Intimacy
Altruism	0,121	-0,008
Courtesy	-0,075	-0,333
Peacemaking	0,034	-0,254
cheerleading	0,083	-0,257

* Significant correlation at level 0.05; ** significant correlation at level 0.01

Table 2: Correlations analysis at the end of the course

	Acceptance	Intimacy
Altruism	0,134	0,210
Courtesy	0,035	0,310
Peacemaking	0,066	0,508**
cheerleading	0,058	0,136

* Significant correlation at level 0.05; ** significant correlation at level 0.01

Learners who show altruistic behavior and donate their time, feel close to their peers and united with them. These results clearly show the development throughout the formation of socio-emotional relationships between learners.

The qualitative data, resulting from the transcription of 20 interviews, underwent a double analysis. The first is a textual statistical analysis and the second is a qualitative analysis by using the conceptualizing categories approach [17]. The categories were extracted from the literature and represent the different indicators of our two research dimensions.

A statistical textual analysis of the frequencies of the words used in the 19 transcribed interviews was conducted using the Iramuteq lexical analysis software. This free software studies groups of significant words and proposes groupings. Three major classes

emerge from the first analyses (Figure 1): A class characterized by the forms "diploma", "career", "professional" which reflects the professional trajectory of the learners as well as their motivation for training. A second class characterized by the forms "group", "phase", "integration" reflects the group organization aspect. The third class is rather related to the moods and feelings of the learners, there are forms related to the dimension of mutual help and the dimension of belonging. This analysis reveals that mutual help takes place in a small working groups.

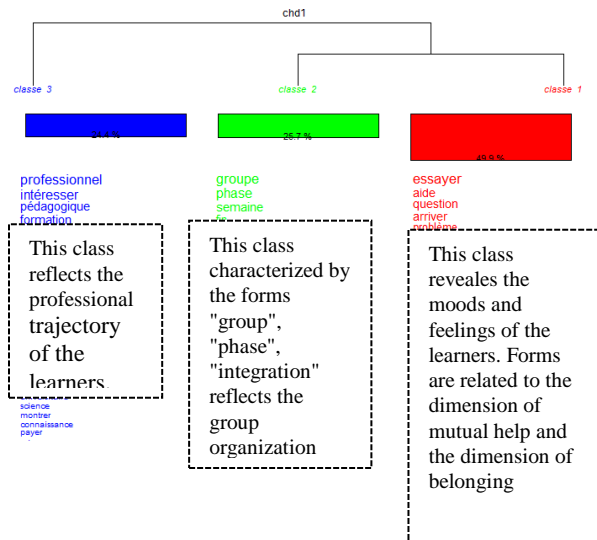

Figure 1. Descending hierarchical classification

A qualitative analysis highlights two group profiles, groups where, understanding and empathy prevail, and groups with difficulties related to both conflicts and agitations between the members of the working group. Given the results, the feeling of belonging is strong mainly in working groups where, understanding and empathy reign. We find in these groups, essentially, altruistic and cheerleading behaviors.

The table of data and variables (Figure 2) shows the results of qualitative analysis. It highlights two group profiles, groups where, understanding and empathy prevail, and groups which have experienced difficulties related either to conflicts and agitations between the members of the working group or abundance of one of the members group. Feeling of belonging is strong mainly in working groups where, understanding and empathy reign. We find in these groups, essentially, altruistic and cheerleading behaviors.

	Entraide				SAS			Groupe (entraide/compréhension)	Groupe (conflit/agitation)
	Altruiste	Conciliation	Courtoisie	Réconfort	Acceptation	Intimité

Figure 2. Data table and variables

Traces analysis of mutual help on the platform's forums is still in progress. 1400 contributions on the thematic forums of the promotion at the beginning of the course were browsed in order to identify those, which describe mutual helping behavior between learners. The first results reveal a weak tendency of learners to provide help to their peers. Requests for help are rather directed towards tutors. The rare helps provided spontaneously by peers categorized as altruistic behaviors mainly concern the organization of the platform such as access to a space, production depot, access to documents. It seems that requests for help are made through non-formal networks [7] or via communication tools other than those present on the platform.

5. CONCLUSION

The mutual help behaviors as we have apprehended them are found in the small working groups, the latter are divided into two groups. Groups in which there is a stable climate of understanding and empathy and groups that have broken up because of the abundance of one of their members, or in which the work has been carried out in anguish and agitation. In the first groups, there is a strong feeling of social belonging (acceptance and intimacy). Learners feel understood and supported and help each other all the time. These behaviors are present at the end of the training course. It seems that the fact of having shared several activities collectively during the whole training favored the development of interpersonal, intimate and regular relationships. However, the feeling of social belonging is low in the groups that have experienced unrest situations or that have broken up due of their member's abandonment. In view of the results, it seems that a third dimension on group dynamics is at the origin of the feeling of social belonging development and the appearance or not of mutual help behaviors.

Structural Explanation of Automated Essay Scoring

Afrizal Doewes, Mykola Pechenizkiy
Eindhoven University of Technology
{a.doewes, m.pechenizkiy}@tue.nl

ABSTRACT

Scoring an essay is an exhausting and time-consuming task for teachers. Automated Essay Scoring (AES) facilitates the scoring process to be faster and more consistent. Nevertheless, AES system lacks transparency about the reasoning behind the score given to the students. This research aims to find a suitable framework for providing an informative score explanation. In our experiment, we develop a regression model using Gradient Boosting, then analyze the overall features contribution and local interpretation of the score prediction. We construct the feedback summary by decomposing the feature contributions and categorizing similar features into a structural explanation. The results indicate that structural explanation can help researchers to recognize and improve the performance of the system when dealing with problems such as gibberish, autocorrect, and spelling errors. The feedback can also highlight the strength and weakness of a student's answer.

Automated Essay Scoring, Structural Explanation, Feature Contribution

1. INTRODUCTION

There is a growing interest to use computer software as tools to facilitate the evaluation of student essays. Theoretically, Automated Essay Scoring (AES) system works faster, reduces costs in terms of evaluator's time, and eliminate concerns about rater consistency. However, AES system lacks transparency about the reasoning behind the score prediction. It is highly needed to build trust in machine learning models trained for classroom contexts [1]. Furthermore, AES system must provide good quality and useful feedback to its users, which can be inspired by the field of Learning Analytics. Researchers from the University of Technology Sydney, Australia, are designing personalized and automated feedback to develop students' research writing skills [2]. They develop a system called AcaWriter for providing formative, actionable feedback on HDR (Higher Degree Research) student writing. The system implements a genre-based approach and the CARS model [3], which describes the rhetorical and linguistic patterns that authors make in their research article introduction. The students stated that AcaWriter helped them think about the structure of their article introduction and focus on the rhetorical moves in their writing. They also found that immediate feedback and text highlighting in the system useful. Pigaiwang [4] is another system providing feedback which is used in more than 1000 schools

in China, including some top universities, such as Tsinghua University, Nanjing University, Fudan University, and so on. Pigaiwang has made an essential contribution to English writing education at university. Pigaiwang provides students with opportunities to revise their writing and continues giving feedback, which improves their writing ability. Revision Assistant is another work which is a tool for providing sentence-level and rubric specific feedback to students [5].

The system feedbacks from previously mentioned studies are mostly provided in the revising phase. Students are expected to revise their work in order to get a better score. In this research, we focus on the final score feedback, which explains to students why the system gives them the generated score. Students are not able to revise their works, but the students can still take advantage of such feedback to perform better in their future exam.

The main contribution of this paper is to enable an AES explanation framework reproducible for researchers to develop their AES system. Unlike the proprietary systems, we develop our system in a transparent way by using open-sourced libraries. We use open and free libraries for the feature extraction, machine learning model training, and the model interpretation. This paper begins with the motivation for finding a suitable framework for score explanation. Then, we present the proposed framework and the experiment settings for generating the score feedback from feature contributions. Afterwards, we discuss the experiment results, system evaluation and improvement. Finally, we conclude our research and plan our future work.

2. PROPOSED FRAMEWORK

Figure 1 describes how the system works. By the time the student submits his/her answer, the raw text answer will be extracted into a feature vector. The regression model will then predict a score for this specific feature vector. The score prediction should be accompanied by the reasoning behind the score in the form of feedbacks. The feedbacks should highlight the strengths and weaknesses of the answer. The strengths are summarized from the feature categories with positive contribution towards the score, and the weaknesses are summarized from the ones with negative contribution.

Feedback in AES system provides transparency about the grading process. This can ensure fairness for all students and make sure that each students' essay is evaluated by the same standard. Students can also identify their strength and weakness, which is beneficial for their future exam. Teachers can take advantage of the feedback feature in AES to assess the performance of the system, and to check whether specific learning objectives have been fulfilled. Score explanation also enables researchers to evaluate and to improve the performance of their AES system by analyzing the model interpretation behind the score prediction.

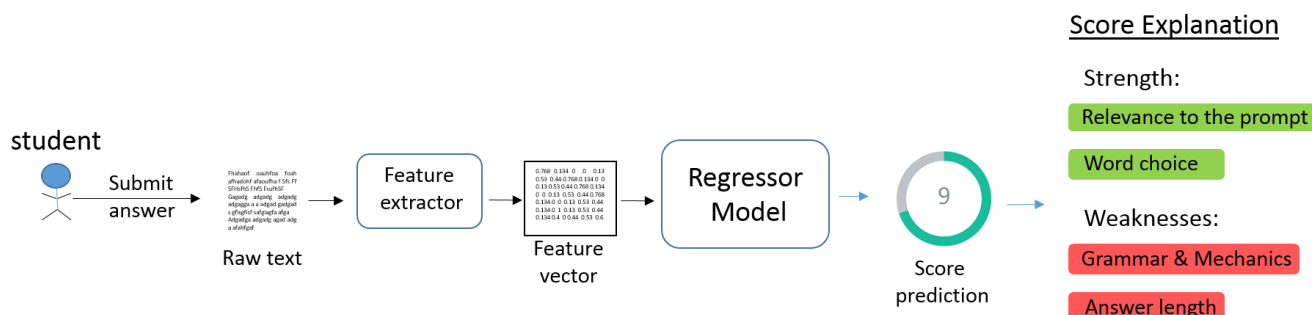

Figure 1 Score Explanation for AES Framework

3. SCORE ANALYSIS FROM FEATURE INTERPRETATION

We develop our Automated Essay Scoring model using Gradient Boosting algorithms. Ensemble model such as Gradient Boosting (GB) is especially hard to interpret because of the complexity. The trade-off between model performance and model interpretability is known among researchers. Generally, a more complex model outperforms a simple linear model. Therefore, we choose to understand the model decision using several interpretation techniques rather than sacrifice the system performance.

3.1 Overall Feature Interpretation

Using XGBoost library, we can train the model and also extract the importance of the features from our model. Identifying the essential features can help us in understanding the behavior of the model in general.

3.2 Score Analysis from Local Interpretation

Local interpretation means that we are interested in understanding which variable, or combination of variables, determines the specific prediction. We use shap values to help in determining the most predictive variables in a single prediction. In AES, the system output is a real number. Each variable contribution will either increase or decrease the output value.

4. EXPERIMENTS

4.1 DATASET

We use the Automated Student Assessment Prize (ASAP) dataset¹, hosted by the Kaggle platform, as our experiment data. In this research, we use specifically dataset #6 from ASAP. The dataset comprises 1800 essays, which then split into the training set and testing set in 80:20 ratio. The score range in this dataset is 0 – 4.

4.2 FEATURES EXTRACTION

The essay features are extracted using EASE (Enhanced AI Scoring Engine) library², written by one of the winners in ASAP Kaggle competition. This features set have been proven to be robust [6]. EASE generates 414-length features. We added one more feature (spelling error) later at the evaluation phase, so that we have 415 features in total.

4.3 MODEL TRAINING

We train the regression models using Gradient Boosting algorithms. We use Quadratic Weighted Kappa (QWK) score as the

evaluation metric. QWK measures the agreement between system predicted scores and human-annotated scores. The mean QWK score for our Gradient Boosting (GB) model using 5-fold cross validation is 0.7667.

5. RESULTS

5.1 Overall Features Interpretation

XGBoost Python package includes the plotting function to reveal the importance of each feature from the model. We show 15 features with the highest importance. Answer length appears to be the most important feature in predicting the essay score. Average word length, prompt overlap ratio, and good n-gram ratio are also among the most important features. Meanwhile, some of the other features are not interpretable because they are merely the bag-of-words representation of the answer. We did not eliminate the bag-of-words features because the model performance, indicated by mean QWK score, is slightly lower without their presence.

Figure 2 The 15-most important features from Gradient Boosting

5.2 Local Interpretation

Local interpretation deals with a single instance prediction, it helps us to analyze the reasoning behind the model prediction. Figure 3 shows each feature's contribution to obtain the score prediction from an essay in the test set. We examined the prediction of essay

¹ <https://www.kaggle.com/c/asap-aes>

² <https://github.com/edx/ease>

sample from the ASAP dataset #6 with essay ID: 15360, taken from the testing set. This answer has a score of 3 out of 4, which is the correct prediction. We can observe that the most influential contributor in predicting the score is the answer length, which has the largest impact on increasing the score. It seems that the student wrote his/her answer above the average length of the other answers. There is a tendency that a longer answer is generally awarded a higher score. Although it remains unclear whether longer essay also provides better ideas and arguments.

Prompt overlap is the second interpretable feature that also improves the score. Prompt overlap means the number of same tokens that are found between the answer and the prompt. Too high overlap score might indicate that the student is not creative or original enough in writing his/her own ideas and words as the answer. However, too low overlap score is also a warning that the answer might be out of topic.

Meanwhile, the average word length affects negatively to the score. Average word length feature can provide an insight that longer word could mean a more sophisticated word choice and help the students to achieve a better score.

Figure 3 GB Feature Contribution for essay ID: 15360

5.3 Structuring the Feedback

We believe that categorizing the feedback in a more structural way is better and can provide a higher level of feedback to the users. Therefore, we propose our structural explanation of score prediction by AES system.

Our framework explains the score prediction in five categories, as we can see in Table 1. The features in the second column are from EASE library, plus one spelling error feature, which we added later in the evaluation and improvement part. Each feature has a different contribution value; it can be either positive or negative. The feedback summary in the first column categorizes similar features and gets its value by summing the contribution values of those features. The summation results with negative values belong to negative feedback, and the ones with positive values belong to positive feedback.

Our first category deals with answer length, and it is the sum of the contribution values of two features; answer length (number of total characters in the answer) and word counts. Relevance factor combines four features from EASE which are related to the degree

of overlap between the prompt and the answer, including the synonyms. Grammar measures the number of good n-gram and its ratio in the essay. The essay is extracted into its POS-tags and we compare them with a list of valid POS-tag combinations in English. The usage of punctuation in the answer, combined with how many spelling errors found, defines the mechanics feedback. Under the assumption that a longer word means a more difficult or sophisticated word, we put the contribution of feature average word length in its own category, namely Difficult Word Usage.

Table 1 Feedback Categories for Score Explanation

Feedback Summary	Contributing Features
Answer Length	- Answer Length - Word Counts
Relevance	- Prompt overlap - Prompt overlap ratio - Prompt overlap (synonyms) - Prompt overlap (synonyms) ratio
Grammar	- Good n-gram - Good n-gram ratio
Mechanics	- Comma Counts - Apostrophe Counts - Other punctuation counts - Spelling errors
Difficult Word Usage	- Average word length

Categories with positive contribution are shown in green. On the other hand, categories which are proven to be negatively affecting the score are displayed in red. We exclude the bag-of-words features from our feedback summary because they are less interpretable. Feedback for essay ID: 15360 is shown in Figure 4.

5.4 Evaluating and Improving the System

It is important to note that all of our feedbacks are based on the general assumption about the text features, and what we can infer from them. In the dataset (ASAP Dataset#6), the final scores are not accompanied by rubric scores or scoring criteria. Thus, we cannot understand the actual reasoning behind the scoring process by the persons who annotate the data. Therefore, we come with our proposed solution to provide score explanation from text feature extraction and see their contribution from the model interpretation. Based on that condition, we can only test our system using some extreme essay samples. The reason is that we are looking for examples that we are confident about the score that should be given.

We can observe three examples of inaccurate predictions or feedbacks from the system in Table 2. The first example (Answer ID: 1) test the system's ability to handle gibberish. We want to avoid users from tricking the system using invalid answers, and undeservedly get a score other than zero. However, the system incorrectly awards the first answer with a score of one. Using our framework, it is possible to analyze the cause of a wrong prediction. The feedback summary in Figure 5 (left) shows that this answer has positive feedback from difficult word usage category. The reason is that the gibberish contains many words with high average word length, which indicates the usage of difficult words from the users. And the usage of more sophisticated words tends to improve the user's score.

Figure 4 System Feedback for Essay ID: 15360

To improve the system, we modified one of our feature in the feature extraction phase. The model will only count the average word length for valid English words. We use Python spellchecking library PyEnchant³ to validate whether each word belongs to English vocabulary. Modifying this feature is able to correct the system prediction. The first answer gets the score of zero, and the system displayed the correct feedback summary, as shown in Figure 5 (right).

Table 2 Evaluating Wrong Predictions

Answer ID	Problem	Actual Output	Expected Output
1	Long gibberish	1	0
2	Long gibberish with inaccurate spell correction	1	0
3	Perfect score (4 out of 4) for an essay that have too many spelling errors	4	3

The second essay (Answer ID: 2) suggests that gibberish possess another form of risk. It seems that the autocorrect feature inside EASE library (Aspell spell checker) may transform the gibberish into a valid word. In the second essay, the sequence of characters such as “sigsigisghsi” is transformed into “zigzags”, “emoybgat” into “embark”, and “adjghadoigda” into “adjudicate”. These valid words, although not meant by the user, increase the average word length value which is correlated to difficult word usage category. Based on this problem, we decided not to implement spell correction while counting the average word length feature. Whereas, spell correction is still applied for the other features. Finally, the system is able to provide the expected prediction for the second answer, which is also zero.

The third answer is actually from the testing set (Essay ID: 15073), and it has the perfect score of 4 out of 4. However, we edited this answer so that it has many spelling errors (15 words). We cannot clarify whether spelling errors is influential in the score according to the human expert who annotated this data. However, we assume that any answer which has that many spelling errors should not be awarded a perfect score. For this reason, in addition to EASE features, we include one more feature, namely spelling errors. It counts the number of spelling errors that appear in the submitted answer.

We rebuilt the Gradient Boosting model with 415 features (414 features from EASE + 1 spelling error feature). The new mean QWK score is 0.7623. Interestingly, the spelling error feature also appear in the top-15 features with the highest importance for the model. Finally, our new model predicts the third answer (Answer ID: 3) with the score 3 out of 4. Moreover, the spelling error feature has the highest negative contribution to the final score for this answer.

6. CONCLUSION AND FUTURE WORK

The purpose of this research is to develop an Automated Essay Scoring (AES) system that can be used in practice. We focus on the score explanation aspect of AES. We demonstrated that our structural explanation framework can be beneficial for researchers to evaluate and to improve the performance of an AES system. Our experimental study shows that by analyzing the system explanation feedback, we can detect faulty behavior of the system prediction such as when dealing with gibberish, autocorrect, and spelling errors problems. Nevertheless, since little is known about the effectiveness of the model and the features for application in different domains, we plan to investigate the suitable design for an adaptable domain setting in the future work. Our current approach still lacks the pedagogical aspects of essay scoring. This is our other future work direction that we expect to improve the system in general and presentation of the focused feedback in particular, thus being more helpful for teachers and students.

Natural Language Processing for Open Ended Questions in Mathematics within Intelligent Tutoring Systems

John A. Erickson
Worcester Polytechnic Institute
100 Institute Road
Worcester MA, 01609
jaerickson@wpi.edu

ABSTRACT

Intelligent tutoring systems continue to enable teachers insight into their students in an immediate fashion. With deep fine-grained data provided to the teachers, they can gain a deeper understanding of the student's learning. While multiple systems exist, most are limited to specific, close-ended questions; these include questions with a set of known acceptable answers, such as solving for 'x' in an equation (i.e. in ' $x+4=6$ ', the clear answer would be 2). Questions of this variety are implemented within these systems and allow for timely feedback to the students. A system can easily decipher certain values to be incorrect answers and help can be offered to the student. While close-ended problems provide a wide range of insights into the student's process, they are often unable to gain the deeper discernment of the student's understanding. Open response questions elicit a greater scope of the student's understanding. However, very few intelligent tutoring systems provide support to teachers and students for these types of questions. Within the few that can, they are not able to offer automation for the process. One of the greater appeals of computer-based systems is that they provide teachers automated grading and give students immediate feedback. It is therefore my goal to further the study and development of automated assessment and feedback tools to support open-ended problems within computer-based systems. Toward this goal, my focus of research is on the development and deployment of automatic grading models, exploration of fairness within such models, and expansion of existing systems to leverage this research.

Keywords

Natural language processing; machine learning; word-embeddings; intelligent tutoring systems; automated grading; automated feedback

1. INTRODUCTION

Intelligent tutoring systems (ITS) have been around for some time, and their benefits have been discussed and noted in

studies such as [13][17]. These benefits, however, have been limited to close-ended problem types. As such, problems with close-ended answers are at the core of most ITS; including ASSISTments [5], McGraw Hill's ALEKSTM and Carnegie Learning's Cognitive TutorTM. This limitation comes from the overall goal of ITS; to provide automated feedback to students and timely reports to teachers about their students. Questions with close-ended answers allow these systems to achieve this goal. For instance, its very simple to set up a system to understand the correct answers when 1/2 or .5 are the only acceptable student answer. Studies such as [14] have discussed why multiple choice questions (close-ended questions) are so appealing: they're easy, accurate and timely to grade. While it is evident that the teachers gains a substantial understanding of the students comprehension from these questions, there is more to student's process of thinking. If the student selects A, the teacher can assert the student's rationale; however, this is a summation from other students selecting the same answer. Open responses questions provide students the opportunity to explain their own personal rationale; giving teachers an even more in depth understanding of the student's process of thinking. Studies such as [6] called attention to the fact that there are vast advantages to a greater spectrum of questions types; when focusing on evaluations with a single question type, it's insufficient in testing the students actual understanding and rationale/critical thinking. By providing support for open response questions, teachers are able to discern, in greater detail, what point the student became confused or if they ever understood. This is also supported by [7] which discussed the wider range of cognition required with open response questions as compared to close-ended multiple choice questions. However, as mentioned earlier, few intelligent tutoring systems support this type of question.

While not the only system to support open response problems, ASSISTments, the system through which much of my prior research has been conducted, is developing tools to improve the support of these problems for teachers. The capability to automatically grade student answers or provide immediate feedback to students is still lacking in comparison to what is possible for close-ended problems. For open response questions, natural language processing (NLP) must be utilized to provide such tool. Additionally, the infrastructure needs to be in place to support these machine learning algorithms for real-time use within classrooms.

John Erickson "Natural Language Processing for Open Ended Questions in Mathematics within Intelligent Tutoring Systems" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 762 - 765

Table 1: Rasch Model Performance from Erickson et al., 2020

Model	AUC	RMSE	Kappa
Rasch Model with teacher component	0.696	1.09	0.162
Rasch Model without covariates	0.827	0.709	0.370
Rasch Model with number words covariates	0.829	0.696	0.382
Rasch Model number words and Random Forest covariates	0.850	0.615	0.430
Rasch Model number words and XGBoost covariates	0.832	0.679	0.390
Rasch Model number words and LSTM covariates	0.841	0.637	0.415

In this paper I will be discussing my previous work, which has attempted to develop machine learned models for automatically grading student open response questions within ASSISTments, in addition to current and proposed future projects pertaining to the further study and development of tools to support these problems in classroom settings. Among this proposed future research, I will describe my intention to study similarity measures to allow students to see similar open ended response rationales to theirs; in this regard, I have drawn inspiration from an existing system, known as myDALITE [2], and propose an extension of this idea utilizing open-ended response problems.

2. PREVIOUS CONTRIBUTIONS

It's clear there is an advantage to developing a tool which can assist in automating open responses in mathematics within intelligent tutoring systems (ITS). If we can bridge the gap between the ITS capabilities within close-ended problems and open response problems, we can further empower teachers with a deeper knowledge of their student's logic. With this, I focused on starting from the ground up. Exploring our ability, within ASSISTments, to automatically grade open response student answers within open response questions in a mathematical domain.

2.1 Automated Grading

While others have utilized a multitude of NLP approaches to interpret and grade open response questions, [16] [15] [12] [18], most have been working with non-mathematical content. Much of the NLP research has consisted of essays and sentences with a standard corpus. This is why so many approaches looked to utilizing deep learning approaches, such as word embeddings Word2Vec [8] and GloVe [10] to gain a vector relational understanding of words. For my research [3], I set out to automatically grade open response questions within the mathematical domain. Contrary to previous research, the corpus within this study was unique in the sense that student answers would be a diverse assortment of words and mathematical functions. Not only was the corpus diverse in words and functions, but the answers were diverse in length. Some student answers consisted of one or two words, while others responded with multiple sentences.

Within this research, the route was taken to approach the NLP task with a wide variety of approaches and methods. With models developed from traditional NLP approaches such as a term-frequency inverse document frequency, *tf-idf* (bag of words model which counts the number of occurrences of the word and re weights the word), to deep learning approaches with word embeddings, a wide spectrum of approaches were attempted.

Overall, 6 different models were developed to predict the student's grade on an open response mathematics question. In Table 1, the baseline model was a Rasch model which didn't take into account any NLP developed models. From there, we supplemented the Rasch model with a *teacher component* and *number of words* covariate. Each of those performed worse than either the *tf-idf*, or the word embedding approaches. By augmenting the models with NLP approaches, the Rasch model was able to improve and provide a stronger performing model with our data (c.f. [3] for further detail pertaining to this study and analyses).

3. CURRENT WORK

While the top performing model in my previous study showed promise with an AUC of .850, RMSE of 0.615, and Kappa 0.430, beating the baseline and all other models, it was decided to ensemble the 3 top performing models. The ensemble, along with the individual previous 3 top models, are now currently being used within a randomized control trial and integrated within ASSISTments. What has become more and more evident is that when utilizing pre-trained word embeddings, there needs to be close consideration of model fairness. As studies such as [1] noted, there can be underlying biases within word embedding models.

3.1 Assessing Fairness

Since multiple of the models within the automated grading study utilize pre-trained word embeddings, my research has progressed towards exploring potential bias within our models. Its imperative that models being implemented within an ITS, or any study, should minimize bias; especially as it pertains to grading. The grades should be based solely on the content, nothing else. As stated earlier, [1] notes that it doesn't matter which embedding approach you use (or pre-trained embeddings in our case), biases, such as gender bias, can sneak in. As the paper references, embeddings can teach models that woman is to homemaker as male is to computer programmer. This is something we explicitly want to avoid in any predictive models within an ITS.

Currently, work is being done to identify potential bias within models from my previous automated grading study. What is imperative is to be able to clearly identify the bias, if there is evidence of bias, and if its coming from pre-trained word embedding (when we account for the different word usages of males and females) or the models the grade predictions are trained with. By developing steps to directly compare models, and word representations, to predict grades given women responses/male responses, we can hopefully identify whether bias is present. We are building our approach from prior works (c.f. [4][9]), and if we can clearly identify which

models have the least amount of bias, then we push those models to production. Additionally, we will be exploring how to handle the bias, if needed, within the suspected models.

3.2 Randomized Control Trial

Currently, my research also is simultaneously being applied to a randomized control trial. This is a study in which the automated grading models are being used to provide student's with their potential grade before they submit an answer. So, once the student's have submitted a answer to the open response mathematics question, one of the conditions will take the strongest performing grade prediction model for the problem and suggest a grade. This grade is then presented to the student and the student will be presented with the option to edit their answer. This poses many interesting questions such as: will the student's edit their answers? If they do, by how much have the answers changed and how much has their grade changed. This is ongoing research and I will continue to develop new models and take into consideration the bias study previously discussed here.

3.3 Comment Suggestions

As discussed previously, one of the main attractions to ITS is the automation. While I have presented multiple models that predict the students grade with reasonable accuracy, within our data, it is clear there is another step. Providing automated feedback is the next optimal tool for teachers and students. Currently, work has been done developing an approach which suggest responses by utilizing similarity calculations. Recently, our team collected data where teachers graded a set of student open response answers. This allowed us to have multiple teachers grade the same student answer, as well. Within this, teachers would grade and create a category which they would place the student answer in. This was performed across multiple problems.

With this, there is now a more robust dataset of answers and associated teacher responses. By utilizing similarity calculations, ranging from Levenshtein distances to SBERT [11], when a student submits an answer to a problems (one which we have previous data on) the most similar student answer on file is calculated and we then can suggest those associated teacher responses with that most similar answer.

Additionally, its being explored how these methods could be validated. For instance, aside from manually looking at the suggested responses, how could there be an offline evaluation of these methods (that does not require teachers to select from the undoubtedly poor suggestions produced by early iterations of such a tool). For each problem, the 3 most similar answer for each individual answer (which has been graded and categorized by our teachers) are selected using both SBERT and Levenshtein distances. From there, it is calculated how many of the teacher categories are the same for the similar answer and the original answer. The method with the most agreement, for each problem, is selected to use for future student answers for said problem.

4. FUTURE WORK

With accurate grade prediction models, a potential method to identify bias, and an approach to selecting similar student

answers, I have a set of approaches which lends itself to the next step I wish to take. I am looking to explore whether we can expand upon just suggesting the student to go back and edit (the randomized controlled trial); can we use NLP to take the students answer, discover which are the most similar, find those similar answers and share their rationale with the student. Then allowing the students the opportunity to go back and either chose their submission or re-write their answers to reflect what they have learned from other similar (or possibly dissimilar) answer rationale. This requires a similarity calculation, a grade predictions (to see if the student's answers and most similar answer would retain the same or different grade) and then a way to show are calculations are accurate. Then once the student's answer has a top 3 similar student answers, the rationale (not answers) are shared. As identified earlier, this practice is in-part analogous to how an existing system, myDALITE [2] functions. It is for this reason that these same methods might be suited to expand upon this idea to provide teachers with new tools that can be used in the classroom.

In this system, students are presented with a multiple choice question and asked to provide an explanation, or rationale, for their work. Students are then presented with other rationales and asked if they would like to keep their answer or if a rationale for a different response has convinced them to change their answer. I wish to explore if this approach could be performed with open response questions. Instead of an initial multiple choice question the student writes a answer and rationale to an open response question and then similar responses are presented, giving the student the option to either change their response or continue. This would require multiple of my previous and current research to prepare such a approach.

This would be a fascinating exploration into how confident a student is in their response. If after seeing others rational, does that convince students to re-evaluate or edit their answers? We may be able to explore what types of answers are confident answers and how much they differ from less confident answers. Additionally, I would like to continue to use NLP to help identify gaming behavior with this type of system; it would be important to identify students answering with "I don't know" types of responses and avoid them simply being presented with other rationales. There are also questions into whether seeing other's rationale could hurt the students learning and cause more confusion. This is an aspect of the study which would need to be expanded upon.

Overall, there have been direct effects of my research, including the implementation of the automatic grader in ASSISTments using the models built in my previous research. Additionally, the current RCT provides an opportunity to see how these predicted grades could impact a student's answer if they were exposed to the grade. Lastly, there is potential for my work calculating similarities between student answers to impact how ASSISTments suggest responses for teachers to students. Hopefully, saving the teacher time and increasing the amount of open response questions given out.

ABSTRACT

The role of self-regulated learning (SRL) behaviors for reading scientific texts has been largely recognized by researchers. Unfortunately, not all learners are effectively self-regulating. To provide effective support for SRL activities, it is necessary for us to understand how students adapt their self-regulation behaviors during reading. This study investigates students' SRL behaviors in science reading using historical data from a K-12 digital reading platform, Actively learn (AL). We analyze reading related SRL in four contexts, such as, domain-specific sequential pattern, question features, question and content difficulty, and teachers' interaction with the platform. We present findings of our work and seek advice on how the insight that we get from these findings can be used in our proposed methodology.

1. INTRODUCTION

Scientific literacy has been a central goal of international science education reforms for last decades, and researchers consider reading science texts as an integral part of science literacy [9]. Despite the importance of reading comprehension, students in the US lack reading proficiency. According to National Assessment of Educational Progress (NAEP) 2019 report, 37% 8th-graders in the US performed at or above NEAP reading proficiency level ¹ and this number is lower than that of 2017. An integral skill for reading is self-regulated learning (SRL) [14]. Unfortunately, the typical teacher/student ratio and teachers' priority for topic completion make it difficult for students to learn and practice reading skills and other SRL skills.

Digital reading platforms can provide opportunities to learn and practice SRL strategies in classroom settings. Retrospective analysis of rich data from digital platforms of can provide insight about students' learning pattern to support tailored interventions by instructors.

The present dissertation proposes four research questions

Effat Farhana "Self-Regulated Learning and Science Reading of Middle-School Students" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 766 - 769

(RQs) to investigate students' reading and reading-related SRL behaviors within the AL platform ². The RQs are described as follows.

- **RQ1. [SRL Patterns and Performance Difference]** *How do students' score connect with their reading and SRL patterns?*
- **RQ2. [SRLs and Question Features]** *How do reading and SRL strategies vary with question features?*
- **RQ3. [SRLs and Content Difficulty]** *How do reading and SRL strategies vary with question and text difficulty?*
- **RQ4. [SRLs and Teachers' Interaction]** *How do teacher interactions with the system connect with students' reading and SRL behaviors?*

In the following subsections we present subquestions, motivations, and possible contributions associated with each RQ.

1.1 RQ1: SRL Patterns and Performance

We split the RQ1 into a subquestion as follows.

RQ1: Which reading and SRL patterns differ between high and low performing student?

RQ1.1 How reading patterns differ for science and social study?

The motivation of RQ1 is to identify reading and SRL behaviors for productive and unproductive students. Additionally, to understand how these behaviors vary for cross domain subjects. Findings of this RQ can be used to develop recommendation system targeted for specific group of students. Also, data driven analysis will be helpful for teacher to make tailored interventions for students.

1.2 RQ2: SRLs and Question Features

To conduct preliminary experiment, we split RQ 2 as follows:

RQ2: How do students' SRL strategies vary with question features?

RQ2.1 Does the association of SRL vary depending on question formats?

RQ2.2 How do other question feature: placement in the text,

²<https://www.activelylearn.com/>

length of question stem, standard usage are connected with students SRL behaviors?

The motivation of this RQ is twofold. First, to understand which question features prompted what types of SRLs? Second, to understand how question features predict performance in assignment score? While previous SRL researchers [1,5] focused mainly on question formats (i.e., multiple choice question, short answer, ...), our research will examine more fine grained question features to understand students' SRLs.

1.3 RQ3: SRLs and Content Difficulty

We will analyze RQ 3 into two phases as follows: *RQ3.1 How do SRL strategies vary with question difficulty?*

RQ3.2 How do SRL strategies vary with text complexity?

Previous two RQs do not distinguish difficulty level between question formats. RQ3.1 assesses question difficulty from student interaction data at *class* level. We compared our proposed approach with the IRT [10] approach.

1.4 RQ4: SRLs and Teachers' Interaction

The first three RQs analyze students SRL behavior considering their study pattern and question and text features. This RQ focuses on teachers usage the AL system and how it contributes to students SRL usage. We will focus on several teacher-behavior including: how frequently teachers are giving feedback and what question standards are they assigning to questions.

2. METHODS AND CURRENT PROGRESS

Currently, the analysis of the first research question, RQ1 is complete (accepted), a subquestion of the second research question, RQ2.1 is complete (accepted), and a subquestion of the third research question, RQ3.1 is under revision. As RQ3.1 is under submission, we present methodology and results of RQ1 and RQ2.1.

2.1 SRLs in AL

Our scope of this study is evaluating students' SRL usage in middle school science reading within the AL platform. AL reading assignments follow Next Generation Science Standards (NGSS) and have *text embedded* questions. Question formats can be multiple choice (MCQs) and short answer questions (SA) (i.e., fill in the blank and free texts). Questions are graded on a [0-4] scale. The platform's developers claim the platform promotes deep learning by close reading: annotating, highlighting, and engaging with text.

We identify three reading support features of AL as SRL: annotating [8], highlighting [13], and vocabulary lookups, as we believe these features serve as proxies for SRL behaviors. Science text involves concept words and vocabulary terms. Students' reading comprehension and motivation has been decreased due to introduction of concept words [4]. Vocabulary lookups help students to understand concepts when they come across new vocabularies. Annotating requires students comprehend text and write down in their own words [8]. Azevedo described taking notes, summarization, and reading notes in context of SRL strategies for science learning with hypermedia [2]. To select texts for highlighting, students monitor information and connect those to their prior knowledge [13].

2.2 Methodology of RQ1

We describe clustering approach followed by generating sequences, and applying differential sequence mining technique with 12,566 science and 16,240 social study student assignment data.

Clustering Students by Performance Score We calculated four types of scores for each MCQ and SA, resulting in eight performance features. These are: first attempt score, last attempt score, *Norm_last*, and *Long Submission*, *Norm_last* is the multiplication of last score by normalized attempts –the ratio of attempts a student's attempt to all students' attempts on that question in a class. *Long Submission* computes proportion of attempts a student made after the median time for all students on that question in a class. After observing the Silhouette width, we applied K-means clustering with K= 4 on both science and social study data .

Coding Student Actions Student activities in the AL are attempts on question answering and SRL. We coded following question answering first attempts of MCQ (M) and SA (S) and resubmissions of MCQ (m) and SA (s). SRL activities are a reading (R), annotating (A), a highlighting (H), and a vocabulary lookup (V). As the AL system does not record student sessions, we relied on a data-driven approach to identify sessions as described by Kovanovic et al. [7] and Adithya et al. [12]. We plotted histograms of time intervals between consecutive actions to identify last action of any time period. Based upon this analysis we chose a cutoff of 30 minutes as a *session* duration. We split all student activities within a single assignment by *session*. We compacted repeated events by + as done by Kinnenbrew et al. [6].

Frequent Patterns within Clusters Within each cluster, we applied the n-gram sequencing technique and include patterns containing at least one letter from the set {R, A, V, H}. Differential sequence mining algorithm [6], requires two parameters: s-support (frequency of a pattern *within* a cluster) and i-support (frequency of a pattern *within* one *action sequence*). We applied s-support = 0.5 to filter patterns exhibited by at least half of students within that cluster. Next, we applied the Kruskal-Wallis test to identify if a significant difference existed in the mean i-support value within the groups.

2.3 Methodology of RQ2

2.3.1 Methodology of RQ2.1

We used hierarchical linear models (HLMs) to model the relationship between observed behaviors and performance, with assignment at level one, nested within students (level two), nested within classes (level three). We built three models for three different response variables: overall assignment score, MCQ score, and SA score. The fixed-effect variables were the SRL features and number of questions in assignment; these variables were at *Level 1*. Assignment, student, and class were all modeled as random intercepts.

3. RESULTS

In this section we present results of RQ 1 and RQ 2.1.

3.1 Results of RQ1

Four resulting science clusters with student counts (n) were: SA_sc (SA performers in science, n = 4,474), MC_sc (MCQ performers in science, n= 3114), L_sc (low performers in science, n =2,363), and H_sc (high performer in science, n =

Figure 1: Science Student Clustering by Score

2,636). Similar as in science student clustering, we observe four different groups in social studies: H_{ss} ($n = 8,948$), L_{ss} ($n = 2760$), MC_{ss} ($n = 2928$), and SA_{ss} (1604). We focused primarily identifying high and low performing student behaviors.

Science Cluster Analysis: Considering H_{sc} vs L_{sc} group, two more frequently used patterns describing SA answering behaviors by H_{sc} students were RS (I-sup_Diff = 0.17, $p < 0.001$) and RS+ (I-sup_Diff = 0.08, $p < 0.001$). RS and RS+ describe reading prior attempting one (S) or multiple (S+) SAs. Thus, reading prior SA attempt were linked to high performances. H_{sc} group students also exhibited more annotation behavior than L_{sc} students (I-sup_Diff = 0.03, $p < 0.001$). Three MCQ attempt related patterns were more exhibited by L_{sc} group students: RM (I-sup_Diff = -0.16, $p < 0.001$), and V+M (I-sup_Diff = -0.001, $p < 0.05$), and RH+M (I-sup_Diff = -0.002, $p < 0.001$). From Figure 1, we observe L_{sc} group students have more MCQ_Long_submissions and lower MCQ_Last scores. We conclude L_{sc} group students struggled in choosing the correct MCQ option.

Social Study Cluster Analysis: Our analysis showed higher-performing students in social study assignments read more frequently before attempting SA and MCQs. Additionally, they looked up more vocabulary. In contrast, low performing students read after attempting SAs. They also had higher resubmission rate of SA questions followed by read event. Our observed patterns explain the way high and low performing students navigated the SA questions. We conclude reading and looking up vocabularies for comprehending the concept prior answering a SA led to score differences for social study subject.

Differential Sequence Mining: Science vs Social Study:

We begin with our results for the H_{sc} vs H_{ss} comparison. Science students exhibited reading behavior *after* SA submissions compared to social studies: SR (I-sup_Diff = 0.16, $p < 0.001$), S+R (I-sup_Diff = 0.12, $p < 0.001$). Examining the descriptive statistics, we noticed the mean SA score is higher in social study assignments (SA First = 2.56, SA Last = 2.62) compared to science (SA First = 2.46, SA Last = 2.58) ones. Additionally, mean MCQ scores of science is higher (MCQ first = 2.80, MCQ Last = 2.89) than those of social study (MCQ First = 2.17, MCQ Last = 2.19). Thus, we compared MC_{sc} vs MC_{ss} and SA_{sc} vs SA_{ss} group. The relatively lower mean SA score in sci-

ence can be explained by SR (I-sup_Diff = 0.16, $p < 0.001$) and S+R (I-sup_Diff = 0.14, $p < 0.001$). Analyzing MC_{sc} vs MC_{ss} group, students with science assignments exhibited more reading behavior before attempting MCQ as described by pattern R+M (I-sup_Diff = 0.0192, $p < 0.001$). Although the two subject domains are different, our analysis shows reading prior attempting a question associated with higher score in both domains.

3.2 Results of RQ2.1

Table 1: Results from HLM Measuring Association between SRL and Science Score

<i>L1 Level</i> (Assignment)	β	<i>B</i>	<i>SE</i>	<i>p</i>
Overall Score				
Intercept		6.533	0.402	<0.001
A	0.055	0.582	0.062	<0.001
H	0.028	0.492	0.072	<0.001
V	0.021	0.275	0.055	<0.001
MCQ Score				
Intercept		5.510	0.369	<0.001
A	0.024	0.206	0.038	<0.001
H	0.016	0.228	0.045	<0.001
V	-0.003	-0.036	0.031	0.259
SA Score				
Intercept		1.699	0.232	<0.001
A	0.040	0.271	0.038	<0.001
H	0.019	0.210	0.043	<0.001
V	0.036	0.289	0.035	<0.001

We report standardized effect size using the formula $\beta = (B * SD_x) / SD_y$ (see e.g., [11]). Table 1 presents our findings. All SRL-related variables had positive and statistically significant association with overall science score. Considering question format, the predictive power of note taking was highest ($B = 0.271$, $\beta = 0.041$, $p < 0.001$) followed by highlighting ($B = 0.210$, $\beta = 0.019$, $p < 0.001$), and vocabulary lookups ($B = 0.289$, $\beta = 0.036$, $p < 0.001$). Considering MCQ format, all but the vocabulary lookups continued to be statistically significant positive predictors of MCQ score.

4. FUTURE WORK AND ADVICE SOUGHT

Proposed Methodology of RQ 2.2 We will use multi-task learning to predict common SRL behavior of students for each question (considering question features) and performance on the question. Thus, we will be able to identify students who need help.

Proposed Methodology of RQ 3.2 We will analyze text readability and complexity including lexical, semantic, and argumentation of the text and SRL usage. To analyze readability of science text, we will examine Coh-Metrix [3] and Python's readability package³. Additionally, we will examine the argumentation analysis in SA response, particularly questions asking for reasoning, e.g. *Why*, *How*, and *Explain*.

Proposed Methodology of RQ 4 To answer RQ 4, we will perform exploratory analysis to answer the sub questions and calculate association with students' SRL behaviors.

A key limitation of our analysis is, we do not know many confounding variables such as, how teachers used AL assignments (in-class, homework assignment, or extra reading), demographic of students, and how they were using SRLs (i.e., teacher might instruct to take notes). Thus, we seek advice on following aspects:

³<https://pypi.org/project/readability/>

- Is our proposed method of RQ 2.2 generalizable to other context, considering the limitation of our study? The motivation of RQ 2.2 is to provide data-driven recommendation to researchers and educators.
- Beyond my proposed methodology, what other analysis could be more beneficial to understand students' SRL strategies in science reading?

Developing Curriculum Analytics and Student Social Networking for Graduate Employability Model

Aleksandr Gromov
University of Technology Sydney
aleksandr.d.gromov@student.uts.edu.au

ABSTRACT

This research focuses on developing graduate employability among university students. The ability to find a graduate position became one of the key tertiary education goals for enrolled students. However, there are lots of factors that affect graduate employability. At the same time, students could be unaware of employability complexity, and their choices may be made blindly. I aim to create a graduate employability model that will help to build a learning path and strategy to the desired career. I am using curriculum profiling, and student performance data to model skills and abilities students develop in their subjects. Besides, I am building a student social network model to analyse students' interactions and ties. Ultimately, my research aims to predict graduate employment and recommend options for better student choices.

Keywords

Graduate employability, curriculum analytics, network analysis

1. INTRODUCTION

Graduate employability became one of the key indicators of university performance. Despite the desire to be standalone institutes and the fact that university education is much broader than simple skill training, universities accepted employability development as one of the goals for tertiary education to satisfy student and industry needs. For instance, graduate attributes, derived from professional industry requirements, are injected into the curriculum, and work-integrated learning became a part of the learning process, aimed at providing work-related experience to students. However, after completing the course, students are not equally employable; one of them find a relevant position upon graduation, while others are stuck without any job offers. What makes one graduate more employable than another?

Literature reveals different factors that affect graduate em-

ployability [1, 8]. They can be aggregated as social, human, behavioural and environmental factors [4]. Social factors define the position of a graduate person in society. As the result, attending a better university, having a large network, belonging to certain social classes will benefit employability chances. In addition, human factors describe personal traits a person have. So, skills developed during the learning course and previous work experience will improve graduate's employability in comparison with another graduate, who is missing these abilities and practice [5]. Furthermore, behavioural factors combine one's attitude toward successful employability [3]. For example, being an active job seeker and dedicated participant of career-related events and workshops makes a difference with a passive waiting for a good position on market demand. Finally, environmental factors are not related to a graduate, but the market situation in general [8]. Economics recession has a negative impact on employability in general, without regards to any personal factors. However, mentioned facets of graduate employability relatively objective and can be analysed by data-driven approaches [2]. There is another, subjective, dimension of perceived employability, which effects chances to be employed based on individual self-evaluation and believes [8].

In my research, I aim to create a student or graduate employability model. However, I understand the complexity of all factors. Moreover, the nature of some factors, such as the economic situation, cannot be altered on a graduate or even university level, falling into the mercy of global processes. Thus, I decided to focus on skills and competences as human factors, and student networks as social factors for my research.

2. GRADUATE EMPLOYABILITY MODEL

In my research, I focus on creating a graduate employability model and investigating the effect of skills, developed by students at university, and student social networks, build through various subjects and courses, on employability after graduation.

2.1 Developing skills through the degree

Students are required to undertake a number of credit points to obtain the degree, which is done by completing multiple subjects. At the same time students are developing their skills and abilities, going through various tasks, assignments and group activities. Knowledge and skill development are integrated into the curriculum and it makes curriculum the source for skill data mining. While curriculum data shows

Aleksandr Gromov "Developing Curriculum Analytics and Student Social Networking for Graduate Employability Model" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 770 - 772

quantitative skill outcomes, students performance will be used for quality research. Clearly, students with in-depth, comprehensive approach will benefit more from the subjects in comparison with effortless students. Implementing these aspects of skill development is part of my project.

2.1.1 Current work

Recently, I created a curriculum profile for the university. Curriculum profile is a hierarchical data structure with skills as the basis nodes, which are aggregated into larger nodes, such as subjects, courses, degrees, faculties or the whole university. Course coordinators benefit from curriculum profile by visualising course outcomes and comparing intended expectations with reality. Students will be able to make more rational choices selecting from the various subjects and navigate their degree with more predictable results.

The curriculum profile is build using off-the-shelf ontology and automated data curriculum data collection. However, the idea behind curriculum profiling requires modular structure with replaceable components. Thus, any ontology that works according to aligned rules can be used as a data source for the curriculum profile via application programming interfaces (APIs).

2.1.2 Future work

Firstly, current curriculum profile is working for one university and has only two modes: the whole university and three selected data science courses. Future development will include all courses from the university available for analysis and comparison.

Secondly, curriculum data is miscellaneous and exist in multiple forms. On the one hand, different universities or even faculties have incompatible curriculum data. On the other hand, some part of the curriculum, such as “Teaching Strategies” or “References”, are less meaningful for text analytics, while others, such as “Content” or “Learning Outcomes”, are richer. The planned research aims to compare each part of the curriculum data to reshape and refine a data source for better text analytics. In addition, it eases the compatibility issues between faculties and universities.

Finally, the created curriculum profile will be matched with student performance data to provide quality perspective on developed skills and market data of employed graduates. It will allow visualising learning path leading to the successful employment, revealing key subjects and skills that helped to achieve it in comparison with other graduates.

2.2 Student networks

Another part of graduate employability model is student social networks. During the learning process, students are involved in multiple subjects. Over the years of study, they interact with hundreds of students, tutors, industry representatives [6, 7]. Even more, indirectly, they can know thousands of other students via the people they know. The process of forming these networks is random. However, networks are reported as an important factor that affects employability [2], and student social networks are a great source of strong and weak ties useful for graduate employability. In my research, I aim to model student networks and predict

how they change the ability to become employed after graduation.

2.2.1 Future work

As part of network analysis, I plan to create a bipartite university network by semester for a selected period of time. The nodes of the network will be students, and edges will be subjects they have selected. Overall network visualisation will help to understand student relationships, identify key subjects and dynamics of network spread. The finalised network will be compared with career data from graduates, who were part of the network as students, to identify choices they made in networking and career outcomes. The contribution of this study will be a student networking model that can predict employment chances for a given student and recommend networking strategies to become more employable.

3. ADVICE SOUGHT

For this doctoral consortium, I seek for advice regarding two questions. Firstly, *what mathematical, probabilistic and statistical methods could benefit my curriculum and network analysis*. I identified several common methods used for other studies. So, skills can be presented as vectors, and further comparison will be reduced to vector comparison, metrics, and space projections. Similarly, I adopted networking methods that allow evaluating network density, clustering, diameter and reach. However, I am looking for more models and methods for my curriculum and network analysis.

Secondly, *are there other factors that affect graduate employability and can be improved at university*. Currently, I use the curriculum data for extracting skills and related careers to identify possible outcomes after completing a subject or course. After that, I will use student performance data to normalise skills outcomes. Also, I use student enrolment data to build bipartite networks. After that, all this results will be matched against actual employment data after graduation. My method creates investigates learning paths and strategies that could lead to successful employment. Thus, I consider human capital (personal skills and abilities) and social factor (student networks), as factors of graduate employability to be improved through the degree. However, I acknowledge the complexity of other factors and their interactions. My research will benefit from experts opinion on developing graduate employability at universities.

Overcoming Foreign Language Anxiety in an Emotionally Intelligent Tutoring System

Daneih Ismail
DePaul University
dismail1@depaul.edu

ABSTRACT

The interactions between learning and emotions are bidirectional. Positive emotions such as motivation, engagement, and happiness induce learning gain. Negative emotions such as anxiety, confusion, and frustration weaken learning achievements. Understanding the learner's mental and emotional state would promote their positive emotion and diminish their negative emotion, which in return, increases learning acquisition. One of the most negative emotions that affect foreign language learning is anxiety. Through our study, we would like to investigate how to detect foreign language anxiety (FLA) then how to reduce and eventually overcome FLA. In the context of FLA, we propose a sensor-free anxiety detector. To overcome FLA, we propose a pedagogical animated agent that provides emotional support. Our preliminary findings showed that a pre-test of a Foreign Language Classroom Anxiety Scale (FLCAS) is effective to predict FLA in the context of an e-learning system.

Keywords

Foreign language anxiety, Emotion, Affect, Intelligent Tutoring System, Sensor-free, Animated Agent

1. INTRODUCTION

Learning and emotions are interrelated. The brain architecture allows complex interactions between emotion and cognition. The brain region work in the integration of the emotional and cognitive process that impact behaviors [18]. A positive, supportive learning environment can escalate positive emotions, which in return, can increase learning gains. On the other hand, a negative learning environment could increase negative emotions, which would weaken learning achievement [9]. Learning a foreign language is challenging because of the cognitive, emotional, and native language proficiency [14]. Anxiety plays critical role in reducing foreign language acquisition [19]. There are several reasons that induce Foreign Language Anxiety (FLA) such as fear of neg-

ative evaluation, communication apprehension, test anxiety [8], task complexity [12], and lack of emotional intelligence [20]. FLA impacts the learner's production and retention [19]. Moreover, FLA produces unwillingness to communicate in the foreign language [15, 17] and reduces the motivation to learn [16]. Furthermore, it divides attention between emotion and cognition which makes performance less efficient [11].

To measure FLA, researchers have used physical measurements [9], self-report [8], and facial recognition [7].

To overcome FLA, researchers have used ITSs [13], robots [3], or games [21]. Each study employs different strategies such as animated agents that provide communicating strategies and affective backchannels [5], soothing music [13], or adjusting the difficulty to suit the learner's level [1, 4, 6, 13].

In our research, we are focusing on foreign language anxiety (FLA). We would like to build a sensor-free emotionally intelligent tutoring system that reduces and eventually overcomes FLA. To achieve our goal we need to understand the causes of FLA, to detect FLA, and to provide interventions that overcome FLA.

The first research question is how to detect the student's anxiety level in an e-learning system. Based on [8], three main reasons produce FLA; fear of negative evaluation, communication apprehension, and test anxiety. In previous studies, we used sensor-lite approach which uses minimal sensors like self-report. We analyzed language difficulty self-report, system difficulty self-report, score of exercise, and pre-test of FLCAS to predict anxiety level [9]. However, for future studies, we would like to investigate sensor-free approach to avoid asking the learner. Consequently, we hypothesized that a pre-test of FLCAS which consists of these three parts would be effective for predicting FLA in the context of an e-learning system.

The second research question is what is the best intervention to reduce FLA in an e-learning system. According to [2], the experimental condition which included animated agents showed positive effects on reducing language barriers while the control group showed shyness and worry when learning Russian as a foreign language. Providing emotional support reduces anxiety [10]. Consequently, we hypothesized that animated agents that provide emotional support are effective for reducing FLA.

Daneih Ismail "Overcoming Foreign Language Anxiety in an Emotionally Intelligent Tutoring System" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 773 - 775

2. PROPOSED CONTRIBUTIONS

Our project is significant because we will use a sensor-free emotionally intelligent tutoring system that overcomes anxiety when learning English as a second language. Using a sensor-free approach will allow the learner to use the product in any environment without the interruptions of a physical sensor. Also, it will be capable of recognizing FLA without asking the learner about their feeling. The ITS will be able to identify learner's anxiety levels and provides adequate support.

The proposed project is unique because it uses animated agents that provide emotional support to reduce FLA. The benefits of this work are decreasing and eventually overcoming FLA. It will help foreign language learners defeat their negative emotions. Moreover, it will generate a relaxing, encouraging, and motivating learning environment which ultimately improves the learning gain.

3. RESULTS SO FAR

3.1 Previous Studies

We did an experiment to identify FLA. 30 participants who are non-native English speakers join the study. They completed FLCAS and demographic information. Then, they answered 27 exercises in grammar, vocabulary, speaking, and listening. We did a correlation analysis to understand the relationship between physical measurements and level of anxiety self-report. We found a significant positive correlation between level of anxiety self-report, blood pressure, heart rate, and eye fixation. Also, we identified FLA by analyzing interaction of learners with e-learning system. We found that time on task, and number of mouse clicks were not significant. While language difficulty self-report, system difficulty self-report, and score of exercise were effective to predict FLA in context of e-learning system [9].

We did other analyses to predict FLA in the context of e-learning system. We predicted FLA based on subject and regardless of type of exercise using pre-test FLCAS components. Depending on exercise type, we used sensor-free prediction using various components of FLCAS. For example, average communication apprehension score was 40% effective to predict FLA in context of listening exercise. Grammar and vocabulary predictions were not significant. For overall FLA, we predicted that average fear of negative evaluation, average communication apprehension, language difficulty self-report, system difficulty self-report, and exercise score account for about 43% of variation in anxiety. We used sensor-lite in this prediction by using language and system difficulty self-report to increase accuracy of prediction.

3.2 Current Study

There will be 180 participants randomly assigned to six groups. They should be non-native English speakers and non-fluent. Their age should be above 18 years old.

The participants start the study by answering some demographic information (native language, age, educational level, and English level). Then they complete FLCAS. After that, they are assigned to one of the six groups (control, textbase supportive feedback, voice supportive feedback, voice feedback, agent supportive feedback, or agent feedback). All the

six groups have the same material which teaches and provide practice in English listening, vocabulary, grammar, writing, and reading. The difference between the groups is in the way feedback is provided. The participants are expected to learn the material then do 20 exercises. After each exercise, there is a self-report that includes language difficulty, system difficulty, and anxiety level. When the participant finishes all the exercises and self-report we send them a \$20 Amazon e-gift card.

For the first research question, we will do a statistical analysis to understand the relationship between FLCAS and learner's current level of anxiety when using an e-learning system. We would like to predict the learner's current level of anxiety using three main components of FLCAS: communication apprehension, fear of negative evaluation, and test anxiety [8]. We will use regression and 10-fold cross-validation to verify the results. For the second research question, we will use Mann Whitney U test to understand which intervention is effective to reduce anxiety.

Then we will use the data from both research questions to build an ITS that reduces FLA.

4. ADVICE SOUGHT

There are two main aspects of research on which advice is sought. First, the set of features used to predict FLA using a sensor-free approach. Our preliminary study showed that using sensor-lite is effective to predict FLA. Sensor-lite uses language difficulty, system difficulty, score, and pre-test of FLCAS as predictors. We would like to use sensor-free without having the language and system difficulty self-report but the model fit drops from 40% to 20%.

Second, algorithms, tools, and applications to build an English foreign language intelligent tutoring system which reduces FLA. So far, we built an e-learning system but we want to upgrade it to be intelligent tutoring system. We tried using CTAT as platform but it was not compatible with the animated agent application we are using. We would like to find the best practices to build the ITS.

5. CONCLUSIONS AND FUTURE WORK

Foreign language anxiety is a major obstacle to learning a foreign language. Identifying FLA then reducing it and eventually overcoming it is a novel approach to improving foreign language acquisition. Using sensor-free anxiety detector and altering the system to reduce anxiety is a promising approach. Through our study, we hope we can predict anxiety using sensor-free approach and reduce anxiety using emotional supportive agent.

6. ACKNOWLEDGMENTS

This experiments was partially supported by a grant from College of Computing and Digital Media at DePaul University. And Media Semantics provided us with a free license for the animated agent.

The Effect of Visual Cues on Cognitive Load Depending on Self-Regulation in Video-Based Learning

Kakyeong Kim
Seoul National University
bettybetty3k@gmail.com

Il-Hyun Jo
Ewha Womans University
ijo@ewha.ac.kr

ABSTRACT

Recently, online learning has been increasingly used due to its advantages that allow people to study anytime and anywhere. Learners, on the other hand, are separated from the instructor in video-based learning, which makes learners difficult to maintain their motivation until the end of the activity. Therefore, it is required to provide instructional treatment so that learners keep their motivation and be immersed in learning. Visual cues, lowering cognitive load, are known a putative way in which learners can distinguish essential information from irrelevant one. The aim of this study is to explore the effect of visual cues on cognitive load depending on the level of self-regulation. The result shows that self-regulation lower cognitive load in the non-visual-cue group as time series, but self-regulation doesn't have an effect on cognitive load in the visual-cue group. This indicates learners in the non-visual-cue group experience difficulty to keep their motivation so that they are hard to put mental effort into the learning. This study suggests that the pupil dilation which reflects cognitive load can be predicted by behavior log which indicates self-regulation. Therefore, it is necessary to enhance learners' cognitive strategies, as well as the reduction of the factors causing unnecessary cognitive load.

Keywords

Visual Cues, Cognitive Load, Self-Regulation, Video-Based Learning, Learning Analytics

1. INTRODUCTION

With the development of technology, online learning has been dramatically increased and people can easily watch videos from different platforms on diverse terminals, such as desktop, tablet, phone [16]. It allows learners to study anytime and anywhere [6]. Learners, on the other hand, are separated from the instructor in video-based learning, which makes learners difficult to maintain their motivation until the end of the activity. Therefore, it is required to provide instructional treatment so that learners can keep motivation and be immersed in learning.

According to Mayer, meaningful learning requires learner to select relevant information, organize the information into coherent representation and integrate this representation into existing knowledge [11]. Multimedia instructions are effective when it is designed in accordance with how human mind works [7].

Kakyeong Kim and Il-Hyun Jo "The Effect of Visual Cues on Cognitive Load Depending on Self-Regulation in Video-Based Learning" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 776 - 780

Working memory has limited capacity when dealing with novel or unorganized information, since it needs more cognitive processing [17]. Cognitive load theory (CLT) is based on the concept that people have a limited working memory and processing capacity [23]. Therefore, the ease of information processing in working memory is main interest of cognitive load theory [13].

CLT consists of three elements: intrinsic load, extraneous load, and germane load [12]. Among them, extraneous load and germane load are affected by instructional design. Extraneous load is risen when unnecessary cognitive processing is needed. Germane load is decreased when learners are not involved in deep cognitive processing, such as organizing or relating the material to prior knowledge [15]. Relatedly, using cues when designing instruction can draw learners' attention to essential elements in learning. Therefore, providing visual cues can lower extraneous load and increase germane load [8].

The relationship between cognitive load and self-regulation sheds light on when and why learners adopt their behaviors and how these behavioral changes are related with cognitive load [5]. Self-regulated learning (SRL) refers to learning with student's goal-directed self-generated thoughts, feelings, strategies, and behaviors [14]. A self-regulated learner plans, monitors, reflects, and adjusts his/her learning process metacognitively, so he/she shows self-paced learning behaviors in computer-mediated learning environment [19, 24]. Learners' regulating behaviors can be assessed as how frequently learners use the learning strategy with the Learning Management Systems (LMSs) in real learning time [4, 18]. Therefore, learners' online behaviors in an e-learning player can be used to analyze self-regulation.

In sum, two hypotheses are created. Firstly, visual cues would be a factor to promote germane load with decreasing extraneous load in time series, which is measured by pupil dilation. Secondly, self-regulation would have a moderate effect on learners' cognitive load. This study aims to explore the effect of the instructional design with visual cues in regard with learners' cognitive load depending on the level of self-regulation.

2. METHODOLOGY

2.1 Participants

Participants were recruited through online notices for a month. Since an ophthalmic disease influences the eye-tracking, participants were asked if they suffered from any of it. A total 100 undergraduate students (46 female, $M = 24$, $SD = 1.79$) took part in the study on a voluntary basis. Then they were randomly assigned to the group with or without visual cues. Among 100 participants, 23 participants were excluded from the analysis due to mechanical faults (e.g., calibration was cancelled or failed, recording was stopped). In the end, 77 participants' data were used and analyzed.

2.2 Procedures

Table 1. Research procedures

Recruitment		Online Notices (Korean Undergraduates)
Screening		Based on Eyesight, Major, Sex
Orientation (5 min)		Explanation about Research and IRB approval, Informed Consent
Experiment (80 min)	Questionnaire (10 min)	Motivated Strategies for Learning Questionnaire (MSLQ)
	Pre-Test (25 min)	6 Multiple-choice Items (from PSAT)
	Video-Based Learning (17 min)	Learning Material for PSAT Problem Solving Strategies
	Post-Test (25 min)	6 Multiple-choice Items (from PSAT)
	Questionnaire (3 min)	The ITC-Sense of Presence Inventory (ITC-SOPI)
Interview (60 min)		Interview with Eye Movement Data

The experiment proceeded in five phases (Table 1). Before starting the experiment, each participant took a 5-minute instruction about the procedure. All the phases were carried by computer. In the first stage, participants responded to Motivated Strategies for Learning Questionnaire (MSLQ). In the second stage, with eye calibration for the eye tracking, a 25-minute pre-test were administered to assess participants' prior knowledge. In the third stage, participants watched the 17-minute video lecture. The video lectures had been designed as two versions whether providing visual cues or not. In the meantime, participants' eye movement and behavior log were recorded with the e-learning player. In the fourth stage, participants took a 25-minute post-test for measuring learning achievement. Finally, they filled out the ITC-Sense of Presence Inventory (ITC-SOPI) scale and then they were interviewed for the comparison between the eye movement and the subjective learning experience response.

2.3 Learning Materials

Learning materials for Public Service Aptitude Test (PSAT) problem solving published by online distance educational institution [26] were used after having been edited. In South Korea, PSAT was devised to test the public officer applicants how well they deal with the public service. For the purpose of this research, the 'data interpretation ability' section in PSAT was only used. This material consists of four problem solving items and total learning time is about 17 minutes.

Two versions of the learning materials were developed with visual cues or without them. Both versions of the learning materials have an illustrated document and a spoken explanation. The experimental group was provided additional colored visual cues when an instructor explains or emphasizes the learning content. That is, colored visual scribbles are added in real time by the instructor while he/she speaks. By contrast, the visual cues were not given to the control group.

2.4 Measures

2.4.1 Physiological measure of cognitive load

Pupillary response measures people's cognitive processing load as a physiological measure [25]. Especially, pupil dilation reflects capacity utilization and relates to cognitive demand [1]. Mean

pupil dilation is a useful for measuring cognitive load [2, 13]. Therefore, mean pupil dilation is measured to analyze participants' mental effort and cognitive load during test and learning time. A Tobii Pro X2-30 eye-tracker and Tobii Studio software was operated at a sampling rate of 30 Hz. Pupillary response was calibrated to the environmental brightness and display luminance for controlling external noise.

2.4.2 Behavioral measures of self-regulation

In order to measure and analyze learners' self-regulating behavior, behavioral log data were collected via e-learning player automatically (figure 1). The learning-related behavior was counted to assess learners' self-regulation [3]. In this study, self-regulation is defined as the sum of frequencies corresponding to every operation to regulate learners' learning and learning environment. Therefore, the frequencies of play, pause, skip, replay, volume change, and rate change were used to analyze learners' self-regulation. The e-learning player was developed by 4CSoft and EduTech Convergence Lab in South Korea.

2.4.3 Learning achievement

Learning achievement was measured as the difference between pre-test scores and post-test scores. Pre-test and post-test were designed based on PSAT. Each test material consists of 6 multiple choice items. Both pre-test and post-test were verified by PSAT subject matter expert.

2.4.4 Questionnaires

2.4.4.1 Motivated Strategies for Learning Questionnaire (MSLQ)

In order to investigate learners' motivation, MSLQ was used. MSLQ is a self-report instrument designed to assess a general cognitive view of motivation and learning strategies [20]. According to MSLQ manual, it consists of two sections: the motivation section and the learning strategies section. Among 81 questions, 10 questions about peer learning, help seeking, and specific course were excluded because they do not fit to this study. Finally, 71 questions were used after adjusting to 5-point scale.

2.4.4.2 The ITC-Sense of Presence Inventory (ITC-SOPI)

When learners perceive presence in distance learning, learners have more sense of being in and belonging in learning [22]. To find out learners' learning experience in video-based learning environment, ITC-SOPI was used. 11 of 38 questions are not appropriate in the context of video-based learning environment, so 27 questions are only used with 5-point scale.

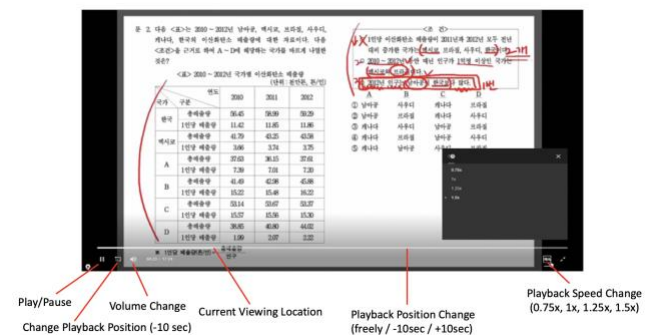

Figure 1. Example of the e-learning player

3. RESULTS

3.1 Descriptive Statistics

Table 2. Means of participants' characteristics

Variables		Mean(sd)		χ^2 (p)	t(W) (p)
		No Cue (n=36)	Cue (n=32)		
Sex (F)		17	20	.040 (.841)	
Major (STEM)		19	15	.236 (.627)	
Age		23.8 (1.80)	24.2 (1.69)		-.897 (.373)
Motivation	Intrinsic Goal Orientation	3.68 (.69)	3.59 (.79)		(.619) (.599)
	Extrinsic Goal Orientation	3.91 (.70)	3.68 (.74)		(700.5) (.125)
	Task value	4.14 (.56)	4.05 (.57)		.674 (.503)
	Control Beliefs	3.81 (.42)	3.80 (.47)		(580) (.965)

STEM: Sciences, Technology, Engineering, or Mathematics.

Total 68 participants' data were used in analysis after 9 outliers of either pupil dilation or behavioral log had been excluded. There is a difference in the participants' pre-test scores (Wilcoxon rank sum test: $U = .883$, $p < .01$). Except for this, all the other differences are not found ($p_{all} = n.s.$, see Table 2). Regarding the pre-test scores difference between two groups, the level of prior knowledge should be considered when interpreting the results.

Because the pupil dilation is affected by time goes, the data should be analyzed as time series [21]. Section division for data analysis was implemented based on four problem solving items at the 17-minute video learning. The mean and standard deviation of pupil dilation in each section were analyzed between groups (No Cue: $M_{Total} = .11(.12)$, $M_1 = .16(.12)$, $M_2 = .13(.12)$, $M_3 = .08(.12)$, $M_4 = .06(.15)$; Cue: $M_{Total} = .13(.14)$, $M_1 = .16(.16)$, $M_2 = .16(.14)$, $M_3 = .10(.15)$, $M_4 = .10(.15)$, see Table 3).

3.2 Pupillary Responses

3.2.1 Pupil dilation in time series

Average pupil dilation is gradually decreased as learning sections proceeded ($F(3, 268) = .5.834$, $p = .001$, see figure 2). The pupil size of all participants in 1st section is higher than those

Table 3. Means of dependent variables

Variables	Mean(sd)		t(W) (p)
	No Cue (n=36)	Cue (n=32)	
Total Pupil Dilation	.11 (.12)	.13 (.14)	-.656 (.51)
Pupil Dilation in 1st section	.16 (.12)	.16 (.16)	.004 (.997)
Pupil Dilation in 2nd section	.13 (.12)	.16 (.14)	-.874 (.385)
Pupil Dilation in 3rd section	.08 (.12)	.10 (.15)	(475) (.218)
Pupil Dilation in 4th section	.06 (.15)	.10 (.15)	-.873 (.386)
Behavior Frequency	18.2 (22.0)	18.8 (20.8)	(518) (.479)
Pre-test Scores	4.03 (.88)	3.47 (.95)	(760) (<.05*)
Post-test Scores	4.89 (1.04)	4.47 (1.19)	(685) (.165)
Improvement in Test Scores (= posttest - pretest)	0.86 (1.25)	1.00 (1.61)	(540) (.655)
Learning Presence	3.05 (.55)	3.16 (.52)	.813 (.419)

of participants in both 3rd and 4th sections (Tukey's post hoc: 1st vs 3rd, $p < .05$; 1st vs 4th, $p < .01$). Similarly, this tendency is shown between 2nd and 4th sections ($p < .05$). This indicates when the sections proceed, the overall pupil size is decreased.

3.2.2 The Effect of Visual Cues on Pupil dilation in time series

The result shows that pupil dilation of the group without visual cues in 1st section is higher than those of participants in both 3rd and 4th sections (Kruskal-Wallis test: $H(3) = 14.203$, $p < .01$; Nemenyi post hoc: 1st vs 3rd, $p < .05$; 1st vs 4th, $p < .05$, figure 3). This indicates that pupil dilation of the group without visual cues is statistically decreased as time goes by. However, this tendency is not shown in the group with visual cues ($F(3, 124) = 1.824$, n.s.).

Figure 2. Pupil dilation in time series
(*, $<.05$; **, $<.01$; error bar, SEM)

Figure 3. The effect of visual cues on pupil dilation in times series (*, <.05; error bar, SEM)

3.2.3 The Effect of Visual Cues on Pupil dilation in time series depending on self-regulation

Multiple linear regression was conducted to test the effect of visual cues on cognitive load depending on self-regulation. Results indicate that the frequencies of self-regulated behavior predict pupil dilation in the non-visual cue group in time series ($R^2 = .137$, adjusted $R^2 = .112$, $p < .001$, see Table 4). Especially, pupil dilation in 3rd section ($B = -.082$, $\beta = -.263$, $SE = .030$, $p = .007$) and 4th section ($B = -.101$, $\beta = -.324$, $SE = .030$, $p = .001$) are predicted in the non-visual cue group. Behavior frequency is also explained in the non-visual cue group ($B = .002$, $\beta = .221$, $SE = .001$, $p = .006$). On the other hand, the frequencies of self-regulated behavior do not predict pupil dilation in the visual-cue group in time series ($R^2 = .043$, adjusted $R^2 = .012$, n.s.).

4. DISCUSSION

Effective instructional design is crucial to maintain learners' motivation and promote cognitive processing in video-based learning. When an ineffective learning material is provided to

Table 4. Multiple linear regression analyses predicting cognitive load and self-regulation

Variables		B	β	SE	p
No Cue	Pupil Dilation in 1st section	.029	.000	.023	.197
	Pupil Dilation in 2nd section	-.032	-.102	.030	.290
	Pupil Dilation in 3rd section	-.082	-.263	.030	.007**
	Pupil Dilation in 4th section	-.101	-.324	.030	.001**
	Behavior Frequency	.002	.221	.001	.006**
Cue	Pupil Dilation in 1st section	.049	.000	.029	.091
	Pupil Dilation in 2nd section	-.004	-.011	.038	.921
	Pupil Dilation in 3rd section	-.060	-.170	.038	.117

	Behavior Frequency	.000	.035	.001	.691

learners, learners have to effort to distinguish key elements from irrelevant information. Being distracted by irrelevant information causes extraneous cognitive load. Based on the CLT and SRL, cueing was used to investigate whether it moderates learners' cognitive load depending on their self-regulatory capacity.

The present study shows pupil dilation of the non-visual-cue group statistically is decreased time goes by. By contrast, there is no statistical difference in the visual-cue group as learning sections proceeded. This implies that learners' cognitive load can be affected by visual cues in time series. Visual cues have an effect on cognitive load in time series within each group. By contrast, pupil dilation was not differed between those groups. This indicates that learners in the non-visual-cue group experience difficulty to keep their motivation and put into mental effort in learning, due to ineffective learning. Next, learners' self-regulated behavior explains cognitive load in the non-visual cue group. In the visual-cue group, learners' self-regulated behavior does not predict cognitive load. Although the interaction between self-regulation and cognitive load is not figured out, the results partially suggest that self-regulation would have the effect on cognitive load within time change by showing different tendencies between two groups.

The previous research said pupil dilation is affected by time and tiredness [9], but the visual-cue group could keep deep cognitive processing and the arousal status until the end of learning. Furthermore, reduction of extraneous cognitive load and increase of germane cognitive load are expected when cue is provided [10]. Consistently, learners' germane cognitive load can be kept and increased when extraneous cognitive load is reduced by the effect of visual cues in this study. Therefore, instructional designers have to consider the effect of visual cues with time series in video-based learning.

This study has several limitations. The first limitation is the difficulty in classifying specific elements of cognitive load. Although, pupillary response is useful way to predict learners' cognitive load, pupil dilation has a problem that pupil dilation can be interpreted in two ways: an increase in germane cognitive load (or mental effort) or extraneous cognitive load (or allocation of attentional resources as task demands increased) [21]. In other words, pupil dilation can reflect both extraneous load and germane load in the same way.

The second limitation is that the group differences in pupil dilation are not figured out, though there are statistically significant differences in time series within each group. This may be caused by the difference of the level of the prior knowledge. Learners' prior knowledge is related to intrinsic cognitive load. This intrinsic load is hard to be affected by instructional design [12]. Considering this, the group's prior knowledge difference may offset the effect of the visual cues on the pupillary response.

Third limitation is about the analytic method of self-regulated behavior. Individual difference of behavior frequency was not controlled in this study. To minimize the variation, behavior frequency was analyzed by the sum over all sections, not by the division of each section. For more accurate measurements of self-regulation, the number of self-regulation behaviors should be analyzed within time goes.

Future research should continue to explore the effect of visual cues on cognitive load depending on self-regulation. With the combination of different measurements for assessing cognitive load, separating specific aspects of cognitive load is expected. When learners' cognitive load is divided and analyzed in each element of cognitive load, designing effective instruction is possible to improve learning effectiveness in video-based learning.

ABSTRACT

The objectives of this ongoing research are to build Real-Time AI-Powered Educational Dashboard (RAED) as a decision support tool for instructors, and to measure its impact on them while making decisions. Current developments in AI can be combined with the educational dashboards to make them AI-Powered. Thus, AI can help in providing recommendations based on the students' performances. AI-Powered educational dashboards can also assist instructors in tracking real-time student activities. In this ongoing research, our aim is to develop the AI component as well as improve the existing design component of the RAED. Further, we will conduct experiments to study its impact on instructors, and understand how much they trust RAED to guide them while making decisions. This paper elaborates on the ongoing research and future direction.

Keywords

Decision support tool, Educational dashboard, Interactive visualizations, Impact, Unsupervised learning, Recommendations

1. INTRODUCTION

A dashboard is a collection of wisely selected visualizations that assists in understanding raw information stored in databases, which helps human cognition [6]. A dashboard can be viewed as a container of indicators [13], but Bronus et al. provided the most accurate definition of the dashboard. Bronus et al. defined the dashboard as "an easy to read, often single page, real-time user interface, showing a graphical presentation of the current status (snapshot) and historical trends of an organization key performance indicators (KPIs) to enable instantaneous and informed decisions to be made at a glance" [5]. This type of visual displays are critical in sense-making as humans are able to process large amounts of data if presented in a meaningful way [17]. The use of learning analytics tools and visualizations have the potential to provide effective support to instructors by helping them to

keep students engaged and achieve learning objectives [15]. Yoo et al. [21] conducted a review of educational dashboards in which they underline the usefulness by mentioning dashboards present the results of the educational data mining process and help teachers to monitor and understand their student's learning patterns. We can apply the same principle to the data collected from a student's quiz questions. The responses received from the quiz can be used for understanding conceptual and meta-cognitive knowledge components [4]. It has also been noted that very few of the deployed learning dashboards addressed the actual impact on instructors [20]. Thus, we see a need for a Real-Time AI-Powered Educational Dashboard (RAED) that is designed for assisting instructors. There are two main objectives of the proposed research.

Objective 1: Build a RAED, which will act as a decision support tool for instructors.

Objective 2: Measure the impact of the RAED on instructors and understand their trust in using the RAED while making decisions.

The proposed dashboard consists of two components - the visualization component and the AI component. The visualization component will present an entire classroom's actions in real-time on the dashboard. This will help instructors to answer two questions: (i) where are most of the students struggling? and (ii) on which questions are most of the students using hints? Answers to these questions can be useful for providing further explanations of certain concepts immediately after the quiz. The AI component of the dashboard will perform unsupervised learning on the collected responses. It will produce clusters of students and also generate recommendations based on the results, which will be displayed on the dashboard. These recommendations made by the AI component will also be included in the visualizations of the dashboard. These visuals will facilitate the instructors' decision-making process. For instance, an instructor may decide to give additional questions or teach a particular concept again after getting recommendations. Therefore, the current research will also be useful for understanding the usability, impact, and trust in the fusion of visualizations and AI in real-time.

Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 781 - 784

Figure 1: Proposed architecture of the RAED

2. RELATED WORK

There is a growing interest in the design and development of real-time systems, such as [14] and [19], that can provide actionable teaching analytics in real-time for decision making. These real-time systems are also beneficial from students' perspective because it gives more time to teachers to provide one-on-one support to students [11]. A user-centric teacher dashboard has been developed by Aleven et al. [2] for understanding interaction data and analytics from intelligent tutoring systems (ITS). Aleven et al. [2] noted that a dashboard could be useful to teachers for helping the class while teaching, and for preparation for the next classes. Diana et al. [7] displayed real-time analytics of interactive programming assignments on an instructor dashboard. From the results, Diana et al. [7] concluded that student outcomes could be accurately predicted from the student's program states. In addition to that, for helping more students in a classroom, Diana et al. [8] also used the machine learning model along with approach maps for identifying and grouping students who need similar help in real-time. Holstein et al. [12] developed the Luna dashboard by collecting data from interpretation sessions and affinity diagramming from middle-school teachers. The goal was to understand the dashboard's usability from the teacher's aspect, as well as its effect on students learning. In a recent paper [10], a wearable classroom orchestral tool for K-12 teachers was tested by Holstein et al. The classroom was represented as a dashboard. In that research, mixed-reality smart glasses were connected to ITSs for understanding real-time student learning and behavior within the ITSs. A framework consisting of five dimensions (Target, Attention, Social visibility, Presence over time, and Interoperation) has also been proposed for the design and analysis of teaching augmentation in [3].

3. PROPOSED CONTRIBUTIONS

This section presents the architecture and design of our proposed RAED. It further describes the features of the RAED and discusses its desirable properties, such as portability and explainability. It also includes information on the current state of our RAED development.

3.1 Architecture and design

The architecture of RAED is shown in Figure 1. Students will get a quiz interface on which they will see the questions and respond to them. The responses will get stored in a database, which can be queried by the dashboard engine. The dashboard engine will be responsible for data preprocessing and data cleaning. The resulting clean data will then be given as input to the visualization and AI components. The visualization component will produce visualizations on

Figure 2: Design component of the RAED

the dashboard, and the AI component will perform clustering of the data in real-time. The results from the AI component will be visualized and interpreted in terms of recommendations. Currently, we have developed a quiz interface¹ for experimental purposes, using R and Shiny. This interface stores results on a Google sheet, and currently this Google sheet acts as our database. The dashboard engine is connected to the Google sheet, which queries data every 6 seconds. Thus, the dashboard is refreshed every 6 seconds.

In this on-going research, we have implemented a design component of the dashboard (shown in Figure 2), which displays real-time visualizations². The essential characteristics of the dashboards noted by Few [9] are taken into consideration while designing our dashboard. We also will be following four elements of the learning analytics process model [20] as a foundation for the conceptual design. These four elements are awareness, reflection, sensemaking, and impact. At the current state, our design includes the first three. Awareness refers to the data, which can be visualized or represented in tables as it streams. Reflection focuses on mirroring teaching practices, and sensemaking can deal with the understanding at-risk students [20].

3.2 Features of the dashboard

We propose five unique features of the RAED. We have implemented a majority of the features, and details are as follows.

1) Interactive visualizations – The visualizations generated on the dashboard are fully interactive (shown in Figure 3) and can be downloaded in Portable Network Graphics (PNG) format. Instructors can interact with them by zooming in, zooming out, selecting different components of the visualizations, etc. These visualizations can also provide meaningful information if the cursor hovers over them. Currently, our dashboard visualizations include scatter plots, bar plots, and histograms. The scatter plot and bar plots are used for understanding the quiz score and number of hints requested by students. Histograms are used to understand the score distribution of the class. Another essential role of the RAED is enhancing the perception of instructors as they can decide what to focus on.

Figure 3: Interactive visualizations of the RAED

ID	Question	Response	Hint	Points
1	1	1	No	2
2	1	2	Yes	2
3	1	3	Yes	2
4	1	4	Option 1	2
5	1	5	Option 2	2
6	1	6	Option 2	2
7	1	7	Option 2	2
8	1	8	Option 1	2
9	1	9	Option 1	2
10	1	10	Option 1	2

Figure 4: Dynamic tables on the RAED

2) Dynamic tables – One of the unique features of the RAED is its dynamic tables. We have provided a summary of the class and scorecard in the form of tables. These tables get updated in real-time, and instructors can search as well as sort the tables. The RAED also provides functionality to download these tables into CSV format for further analysis (shown in Figure 4).

3) Portability – The dashboard is designed in R and deployed on the Shiny server. This dashboard is portable and can be connected to any database or tool.

4) Real-time – The dashboard provides updates of the data every 6 seconds, which can help to capture student’s real-time interaction during the quiz. Further, we provide the additional feature of pausing and resuming real-time streaming. This feature can be especially useful when analyzing the dashboard.

5) AI and explainability – This feature is currently under development. We plan to employ explainable AI on the dashboard. It will help instructors to understand how AI provides results to the dashboard, i.e., how it chooses the number of clusters and how it produces recommendations.

4. FUTURE DIRECTION

The future direction of this research is to develop a prototype of the RAED, test it in classrooms, and then conduct surveys to measure its impact and trust. Future research will be held in the following four phases.

- **Phase 1 (AI component):** Currently, we can store

student ids, names of the course topics, responses, scores, whether hints are used, and what is the total number of requested hints. We will be using this information for clustering students and generating recommendations for them. The process of clustering can be useful for focusing attention on students with similar characteristics and learning rates. This information can help instructors to form support groups within the class and to provide personalized guidance to particular students. For example, students from the high-performance group can be paired with students in the low-performance group, which can help to improve performance.

In the first step, similar students will be identified by performing clustering on the data. The goal of this step is to identify three clusters (high performance, average performance, and low performance). It is essential to visualize the process of clustering for implementing explainable AI. Thus, the implementation of Agglomerative Hierarchical Clustering makes a suitable choice. Using this approach, clustering process will begin with points as individual clusters, and at each step, the similar points will be merged into a larger cluster [18]. This entire process of clustering can be visualised by plotting a dendrogram, which fulfills our goal of explainability. The other advantage of using Agglomerative Hierarchical Clustering is that it provides good results when given small datasets as input [1], as is the expected number of students in a class. In the next step, information of students from these clusters will be obtained, and a list of concepts that students need to improve will be derived from the responses. It will also provide suggestions on pairing students during in-class activities. This information will act as recommendations to instructors and can also help to understand conceptual as well as meta-cognitive knowledge components of the class.

- **Phase 2 (Design):** We will focus on the design aspect of the RAED using the iterative design process. In this step, the prototype will be shown, and functionalities will be explained to the instructors for getting their insights on RAED. Surveys will be provided to the instructors for evaluations and to know their additional needs. Questions in the survey will be based on the questionnaire created by Park et al. [16].

The results will help us to get inputs on information usefulness, visual effectiveness, appropriateness of visual representation, user-friendliness, and understanding of the information. Changes will be made in the design after analyzing responses from the survey. In the next iteration, RAED will be shown again to the instructors, and their feedback will be requested. In this way, at the end of this phase, the prototype will be ready for testing.

- **Phase 3 (Testing):** In this phase, the prototype will be tested in classrooms. The quiz interface will be provided to students, and RAED will be made available to instructors. This phase will help us understand the technical problems that may occur, such as server issues. Improvements will be made as necessary.

- **Phase 4 (Survey):** In this final phase, surveys will be provided to instructors to understand their changes in behavior, the achievement of the objective, trust in the system, effect on motivation and decision making due to the RAED. The responses will help us to measure the impact of the RAED on the instructor's decision making. It will also give us insights about the trust instructors have in the RAED.

5. ACKNOWLEDGMENTS

The authors would like to thank DataLab at George Mason University for their support. The authors also would like to thank Dr. Olga Gkountouna for useful feedback on this work.

Estimation for cognitive load in Video-based learning through Physiological Data and Subjective Measurement by Video Annotation

InHye Lee
Ewha Womans University
22netaurus@gmail.com

ABSTRACT

When designing a video-based learning such as MOOC, it is very important to understand the cognitive aspects of learning and reflect them in the design. Many studies use subjective and physiological data as indicators of cognitive load. To fully understand the cognitive load, we need to understand both of them simultaneously. Therefore, this study is to investigate whether eye data (Mean Pupil Dilation, Mean Fixation Duration) predicts subjective cognitive load during video learning. Furthermore, as a second research question on a broader scale, we examined whether eye data predicts high and low states of subjective cognitive load during video learning. Through this, we expected to find the possibility of Video Annotation and Eye data as a way to measure Cognitive Load during video learning. The experiment was conducted in a controlled laboratory environment with 100 students. In the video learning situation, the learner's eye data was measured using an eye tracker. Immediately afterwards, a video annotation (VA) interview technique was used to put markers according to the cognitive load types such as A (Understanding), B (Easy), C (Complicated), and D (Discomfort). The collected data will be analyzed by Support Vector Machine, a machine learning technique that is considered appropriate for the physiological data.

Video-based learning, Physiological data, Eye data, Video Annotation, Eye tracking, Cognitive Load, Support Vector Machine

1. INTRODUCTION

Recently video-based learning has become a common form of learning for both corporate and school education as well as open contents such as MOOCs and Coursera. However, since instructors and learners are separated in time and space in video-based learning, it is difficult to immediately reflect learner's response to the instructional design. In addition, universal instructional design does not reflect the characteristics of each learner. For this reason, universal instructional design in video-based learning tends to result in learner neglect or dropout, as can be seen in MOOC's high dropout rate. Therefore, instructional design considering the learner's learning process is important in

video-based learning.

Cognitive load is the one of the most remarkable factors in human learning process. In many studies, including Moreno's work [8], we have accumulated evidence that cognitive load is a reliable factor for effective video-based learning design. In addition, various data left by learners during video-based learning are important resources for instructional design considering individual cognitive load. However, most pedagogical studies measure the learner's internal processes using a psychometric scale. This approach has problem to be solved that memory distortion may occur because it is usually measured after learning. Hence, physiological data are used as an objective measurement index. Especially, eye data can be measured in real time. Moreover, in case of pupillary reflex, it is under control of autonomous nervous system and cannot be voluntarily controlled by the subject. However, despite its advantages, it is sensitive to environmental variations such as luminance [3][5][18]. Therefore, using both psychometric subjective scales and eye data can complement each other.

In this study, we will examine how the physiological data predicts the subjective measurements of learners using Support Vector Machine which is machine learning techniques. Also, in case of subjective measurement, video annotation is used to prevent memory loss after learning. This study proceeded with Video Annotation right after eye tracking experiment. This study aims to discover the possibility of using both of physiological data and Video Annotation to measure cognitive load reliably. Through this study, we expect that indicators of cognitive load will be used as more reliable resources for video-based instructional design.

2. LITERATURE REVIEW

2.1 Cognitive Load Theory

According to the Cognitive Load Theory proposed by Sweller [9], Cognitive Load is defined as the sum of mental activities imposed on human working memory when processing new information. There are three types of cognitive loads, and each type of cognitive load is additive. First, external cognitive load is a cognitive load imposed by inappropriate instructional design, which can be controlled by efficiently structured and designed learning environment and tasks [11].

Since external cognitive load is not a desirable load for learning, it needs to be minimized through instructional design. Second, the intrinsic cognitive load is the cognitive load caused by the element interactivity of the learning contents. As the task becomes more complicated, the intrinsic cognitive load felt by the learner increases. Finally, the germane load is the cognitive load used to handle schema acquisition and automation in learning. Germane

In-Hye Lee "Estimation for cognitive load in Video-based learning through Physiological Data and Subjective Measurement by Video Annotation" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 785 - 789

load is a very important load to facilitate learning. If these three types of cognitive loads exceed working memory, information processing, including learning, will be threatened. Therefore, the purpose of instructional design is to minimize the external cognitive load and increase the intrinsic load within the learner's memory capacity. Instructional design considering each type of cognitive load presented by Cognitive Load Theory can provide more customized learning for individual students[19].

Cognitive Load Measurement Methods

The development of a method to measure cognitive load more effectively plays an important role in the study of cognitive loads [10]. Researches measuring cognitive load are largely divided into subjective and objective measurement methods. First, the subjective measurement method is measured through rating scales. This subjective item tool has the advantage of being able to measure each element of cognitive load separately. It is also widely used to measure cognitive load in many studies because it can be measured by learners relatively easily[13][14]. Cognitive Load mainly uses subject ratings of mental effort and task difficulty as indicators of cognitive load[12]. However, the subjective scale has a disadvantage in that the memory is distorted because it is influenced by the learner's bias and occurs after learning. In addition, there are objective measurement methods measuring through physiological data using EEG, eye data and skin sensitivity. In particular, the eye data measured by the eye tracker has attracted attention in recent studies[18]. Since eye data is measured at the moment of learning, it can be measured without affecting learning process. However it has a problem to be solved that it is sensitive to the external environment.

The preceding studies comparing subjective data and eye data are as follows. Korbach, Brünken and Park[6] set up three groups that distinguish external, intrinsic, and intrinsic cognitive loads, and then identified the differences through rhythm methods, subjective ratings, and eye data. As a result, both objective and subjective measures significantly distinguished the differences between groups. Most of the studies that classify cognitive load use subjective measurement methods or use both objective and subjective measurements together. However, studies that deal with both subjective and objective data should be preceded more by classifying cognitive load types in various learning contexts.

2.2 Eye data

This study utilizes Pupillary data and Fixation Duration among eye data. For Pupil data, Mean Pupil Dilation(MPD) is used. MPD has been used as a reliable indicator of cognitive load. In most cases, MPD expands in according to increasing cognitive load[1]. However, as mentioned earlier, it needs to be careful when collecting because it responds to not only psychological changes but also visual stimuli caused by environmental changes. Marquart & Winter[7] measured cognitive loads while the driver was driving using blinking eyes, eye fixation, and pupil dilation indicators. As a result, the expansion of the pupil size was observed statistically when the workload occurred during operation. Fixation Duration also can be used to measure the attention that individuals have paid to stimuli which means that Fixation Duration can be one of factors that increase cognitive load[16].

2.3 Video Annotation

Video Annotation is a kind of retrospective technique. Retrospective technique is a follow-up observation method that uses visual or auditory clues to access a subject's memory and recall the thoughts and strategies that occurred while performing a specific action or task[2]. The video annotation presents the learning video to the learner immediately after the learning ends for recall. Learners stop the video where they want it and record their thoughts[4]. It is a promising approach to facilitating video retrieval but also it can avoid the intensive labor cost of pure manual annotation[17].

The study used Techsmith's Morae software for video annotation. Notes settings were A(Understanding) which indicates germane load, B(Easy) and C(Complicated) which indicate low and high intrinsic load and D(Discomfort) for extraneous cognitive load.

3. METHODS

3.1 Research Question

The research questions of this study are as follows.

1. Does eye data (pupil response, eye fixation duration) predict subjective cognitive load during video-based learning?
2. Does eye data (pupil response, eye fixation duration) predict the total amount of subjective cognitive load(high and low) during video-based learning?

3.2 Experiment Settings

This study was approved according to the Institutional Review Board (IRB) Institutional Review Board (EBH), and was conducted on 100 male and female college students.

3.2.1 Procedure

This study was conducted in the Edutech Convergence laboratory at Ewha Womans University in order to provide an optimal environment in consideration of illuminance and noise that affect measurement data. The window in the laboratory was covered so that the laboratory was not affected by light intensity. The height of the chair and the pedestal were adjusted to each subject just before measurement, so that the environment of the participant's pupils was accurately tracked. The experiment time for each subject lasted about 100 minutes and one person at the same time.

Figure 1. Experiment procedure

As shown in Figure 1, the study purpose, the duration of the experiment, and the precautions related to the experiment were announced before entering the controlled experiment site. Subsequently, the basic personal information and learning motivation strategy which is called MSLQ[15]. They were collected through the 5 Likert questionnaire. After the survey, the subject enters a laboratory where light and noise are controlled. The controlled laboratory is shown in Figure 2.

Figure 2. Environment setting for eye tracking

Figure 3. Environment setting for video annotation

According to Tobii eye tracker's manual, it was recommended to keep the distance between the study subject and the measuring device constant for accurate measurement. Chin pedestal was used to maintain constant distance. Concerned about an increase in the subject's fatigue, they were guided to rest for 30 seconds at the end of each step. In each step (pretest, video study, posttest), the sequence was set to stare at the front for 10 seconds to find the baseline of the pupil.

As shown in Figure 3, video annotation was performed in the room prepared for the interview. To implement a special interview method called video annotation, we used TechSmith's Morae program.

3.2.2 Participants

This study estimates the cognitive load in the video-based learning situation and recruits the most accessible adults (college students) in the video-based learning context such as MOOCs and Coursera. For accurate measurement, only those who do not have eye-related diseases and who can replace glasses when wearing lenses were allowed to participate in the experiment. In addition, the gender and major categories were selected to be evenly distributed. Even if there were no eye-related diseases, if the eye tracker did not track the eye during calibration, the ear was taken because no data could be collected. In addition, subjects whose data exceeded the recommended range for eye tracking during pretreatment or missing more than 50% of the data due to missing values based on pupil range outliers were excluded from the analysis.

Of the total 100 participants, 96 participated endlessly without returning home halfway. Among them, 82 were studied except for missing values. Thus, 18% of the participants were excluded from the analysis. The demographic information of the study subjects used for analysis in this study is as follows.

Table 1. Demographic Information of Subjects(n=82)

Gender	Male	39
	Female	43
Major	Liberal arts	42
	Science and Engineering	40

3.2.3 Stimuli

The stimuli given to the subject during eye tracking are as follows.

Pre-test and post-test

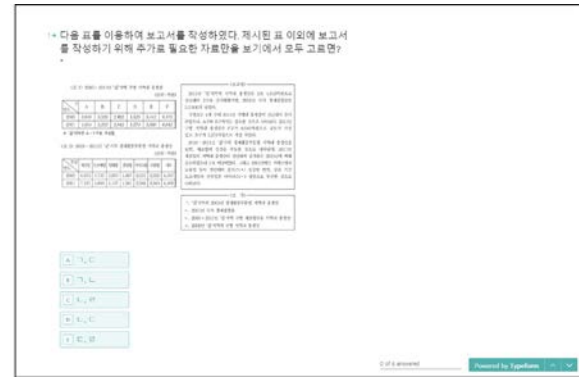

Figure 3. A screen shot of pre-test

The pre- and post-examination tests consisted of PSAT questions, a test to select South Korean civil servants. The problem is that both the pre- and post-test have a total of six questions and the time limit is 25 minutes.

Video-based learning

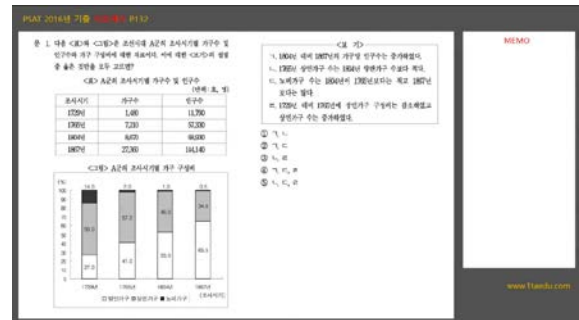

Figure 4. An example of video screen

As shown in Figure 5, video-based learning is a learning video that teaches PSAT problem solving strategies. In order not to distract the learners' attention other than the contents of the study, the lecturer was selected as a video in which the lecture was conducted only by voice.

3.2.4 Instruments for measurement

Eye tracker

In this study, Tobii Pro X2-30 (30Hz) eye tracker was used to measure 30 frames per second to measure pupil response and eye fixation duration. As can be seen in Figure 2, pupils can be measured non-intrusively simply by keeping the 50 ~ 70cm distance between the measuring device and the subject without additional wearing. Therefore, data can be collected without pre- and post-testing and video-based learning. The collected data was extracted in the form of csv data that can be analyzed using Tobii Pro Studio program, Excel and R Studio program.

Morae for video annotation

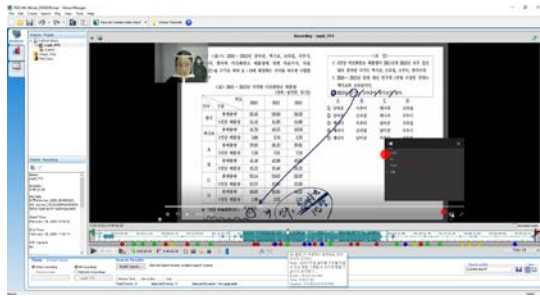

Figure 5. A screenshot of Morea for video annotation

Figure 6 shows an example of TechSmith's Morae program. As you can see from the enlarged figure, Morae program screen is replayed by the learner at the time. In the upper left corner, the face image of the learner was taken in the previous experiment. The screen shows the points and paths that the subject looked at then with red dots and lines..

The learner entered the thoughts and feelings he had heard at the moment while looking at the screen, his gaze, and facial expressions that he stared at in the previous experiment. Press Ctrl + M to select one of A (Understanding), B (Easy), C (Complex), or D (Discomfort), and then type the sentence directly for the reason. During the direct entry by the subject, the researchers looked at the screen together and helped when confused about which markers to choose.

3.3 Data Analysis

3.3.1 Datasets

The variables selected for the research question are shown in Table 2 below.

Table 2. Variables(Eye data and video annotation)

Variables		Description
Eye data	LocalTime Stamp	Timestamp counted from the start of the recording
	GazeEvent tType	Type of eye movement event classified by the fixation filter settings
	GazeEvent Duration	Duration of an eye movement event
	Distance Right/Left	Distance between eyes and the eye tracker
	Pupil Right/Left	Estimated size of the right(left) eye pupil
	Validity Right/Left	Indicates the confidence level that eyes have been correctly identified
Video Annot ation	Elapsed Time	Timestamp when subjected noted markers
	Details	Indicate markers which subjects noted

3.3.2 Data pre-processing

As mentioned earlier, even if the experiment was completed, the subjects whose data were more than 50% that could not be used for analysis due to missing values in the preprocessing process were excluded from the analysis. Eye data was excluded from the analysis when the recommended distance was out of 50 ~ 70cm. In the case of the pupil size, the difference between the pupil size

of the left and the right is more than 0.4 mm and was also determined as the pupil portion.

In the case of the pupil size, the average of the baseline measured in each section was calculated, and then derived by subtracting the baseline from the measured pupil size. Therefore, because the pupil size measured every second is the baseline minus, the pupil expansion indicators are positive when the pupil is larger than the baseline, but may be negative when the pupil is reduced.

After that, the LocalTimeStamp and Elapsed Time variables of the eye data were changed to the same time expression, and then preprocessed by matching the note and eye data shown by time zone. Therefore, the variables used for the actual predictive analysis are as follows: Markers from Video Annotation (VA), Mean Pupil Dilation (MPD), Mean Fixation Duration (MFD)

The first research question analyzed SVM classification of preprocessed data. The second study divided the A (Understanding), C (Complicated), and D (Discomfort) groups with high cognitive loads and the B (Easy) markers with low cognitive loads. Since the high group of the three markers combined had more than three times the number of data, we randomized and set the same number as the low group. After that, we checked whether the high and low groups were predicted.

3.3.3 Data Analysis

The analysis was performed using R Studio, a statistical analysis program. The preprocessed data is analyzed by Support Vector Machine (SVM) technique. The reason for analysis by SVM method is as follows. First, because of experimental data characteristics. Since eye data is measured at 30 frames per second for 82 subjects, a very large amount of data is collected. In addition, due to the nature of the physiological data, even a laboratory set up is susceptible to microenvironmental influences. Therefore, we chose SVM that is less affected by outliers and has higher accuracy. Second, SVM has the advantage of less overfitting than other neural network techniques. Finally, it is suitable for the markers (A, B, C, D) variables obtained through video annotation because they can be classified and predicted simultaneously.

The first research question analyzed SVM classification of preprocessed data. The second study divided two groups with high cognitive loads which consists of A (Understanding), C (Complicated), and D (Discomfort) and low cognitive loads which consists of B (Easy) markers with low cognitive loads. Since the high group of the three markers combined had more than three times the number of data, we randomized and set the same number as the low group. After that, we checked whether the high and low groups were predicted.

ABSTRACT

Learners are being exposed to abstract skills like innovation, creativity and reasoning through collaborative open-ended problems. Most of these problems, like their real-world counterparts, have no definite starting or ending point, and have no fixed strategies to solve them. To help the learners explore the multiple perspectives of the problem solutions there is an urgent need for designing formative feedback in these environments. Unfortunately, there are barriers to using existing EDM approaches to provide formative feedback to learners in these environments: (1) due to the vast solution space, and the lack of verifiability of the solutions it is impossible to create task and expert models, thus making the detection of the learners progress impractical; (2) formative feedback based on individual learner models does not scale well when many learners are collaborating to solve the same problem. In this work, we redefine formative feedback as reshaping the learning environment and learners' exploration paths by exposing/enlisting "fugues" as defined by Reitman [28]. Through a case study approach we, (1) validate methods to extract learners' "fugues" from a collaborative open-ended museum exhibit, (2) design formative feedback for learners and educators using these extracted fugues in real-time, (3) evaluate the impact of exposing fugues to group of learners interacting with the exhibit.

Keywords

Data-driven, Formative feedback, Open-ended learning environments, Ill-defined problems, collaborative learning

1. INTRODUCTION

With the recent advances in storage and retrieval methods of data and increased computing power the way we look into learning processes has changed [2]. We are now able to collect data to the most minute detail which was not possible in the absence of tracking devices and computer-based interactive learning environments. These improvements in instrumentation make rich interactive "classrooms

of the future" [32] amenable to computer-driven monitoring and support, but it's not a matter of just applying existing analytic approaches. The vast majority of learning analytic techniques are predicated on assumptions about learning environments that may not hold. While there have been many examples of using data mining to track students' progress through interactive learning environments using log files (e.g., [12, 1, 23, 10, 27, 3, 5, 14, 6, 24]) most of these learning experiences have been developed with reference to expert envisioned solutions which act as a strong model that the learners need to follow [9]. For example, learners are given a well-defined, fixed goal with known, optimal number of steps to reach this goal, and known, fixed number of choices that can be made by the learner at each step. In such circumstances any user action can easily be judged as taking them closer to or farther away from the goal [20]. This clarity often underpins the structure of model based Intelligent Tutoring Systems (ITS), which typically combine exhaustive, a priori "strong" models of the content domain and prior learner performances with models of the student's current progress to generate guidance [35]. These well-constrained problem spaces have successfully been used by data miners, who rely on a priori models and on post hoc analysis to provide formative feedback to the students [10, 3] or to their teachers [23], to provide formative feedback to the environment designers [12, 23], or to provide evaluative feedback on the nature and scope of mistakes made by learners in the environment [1, 27].

However, these constrained problem spaces often do not reflect problems found in the real world. Real-world problems often possess multiple solutions, where each can be attempted with multiple alternative theories, or sometimes lack the theories to verify solutions; or possess multiple task structures leading to overlapping sub-problems which thus demand novelty rather than replication from the learner [19, 9]. Additionally, these problems are often solved by groups of people who each bring in a new perspective, perspectives which are critical to preserve in order to develop workable solutions for real-world problems like climate change, social change and many others. Due to the varying dimensions wherein open-endedness can exist, the notion of open-endedness is quite vague, and oftentimes it is difficult to differentiate open-ended problems from well-defined problems; in actuality these problems seem to exist on a continuum. Simon [31], defined open-ended problems as having three features: (1) indefinite starting points, (2) indefinite ending points, which constitute goals - either are not clearly de-

Aditi Mallavarapu and Leilah Lyons "Exploration Maps, Beyond Top Scores: Designing Formative Feedback for Open-Ended Problems" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 790 - 795

finer or are complex and imprecise, and (3) with no clear strategies to solve the problem. While presenting learners with simplified and constrained problems can be a good way to help them come to understand the core properties of a domain, exposing learners to less constrained, more open-ended problems can help them get experience with disciplinary processes and dispositions [20]. Owing to the recommendations of many educational standards both formal and informal educational settings are giving the learners opportunities to practice these disciplinary processes and develop disciplinary dispositions by exposing the learners to open-ended, project-based student centered approaches [29]. Since these problems expose the learners to a rather large solution space, some researchers have argued that open-ended learning environments, and the exploratory learning styles often promoted to go along with them, are simply not workable in educational settings [17]. While other educational researchers have argued that rather than giving up on exposing learners to open-ended problems, educators and researchers should instead seek to support learners in their explorations via proper supports [13], like scaffolds and formative feedback. We argue that data mining offers great potential for supporting open-ended learning via data-driven formative feedback.

1.1 Formative Feedback

Formative feedback has been defined as “information communicated to the learner that is intended to modify the learner’s thinking or behavior for the purpose of improving learning” [30]. Formative feedback has been used extensively to support learners while solving well-defined problems, as when a learner is given a hint based on his “distance” from the goal, or a suggestion based on the expert model to get him “closer” to this model. These forms of formative feedback are inherently tied to an assumption of one fixed goal, making them unsuitable for open-ended problems which can have a dynamically evolving state space thus demanding that the learners’ goals evolve with them. Moreover, it can be challenging to fit a fixed goal perspective to collaborative learning environments, both pragmatically (instrumentation is a challenge) and conceptually (how one can go about ascribing “credit” to multiple learners when they jointly create a solution - is a theoretically undefined proposition - we don’t yet have theories of learning, and thus metrics, that fully account for and embrace the multifaceted ways groups of learners support one another and their joint endeavors).

Summarizing, there are two main barriers to adapting existing formative feedback approaches for use in open-ended collaborative learning environments: (1) due to the vast solution space, and the frequent lack of solution verifiability, it is difficult to create an exhaustive task or expert models, thus making the detection of the learners’ progress challenging [25]; (2) Most of the formative feedback in well-constrained problems is based on individual learner models, which does not scale well when many learners are collaborating to solve the same problem, a known problem in the field. To supply formative feedback for open-ended collaborative learning environments, a fundamental re-conceptualization of how formative feedback is structured, and the techniques used to distill it from collected data, are needed.

2. PROPOSED CONTRIBUTION

This research proposes to re-conceptualize formative feedback (and how it is derived from logged data) so as to support learners in open-ended, collaborative learning environments. First, we make the deliberate decision to step away from measuring or modeling individual learner “progress” - rather than placing the learner, and his or her actions, at the center of our analytics, we instead place the *solution space* at the heart of our analysis. We conceptually relate formative feedback for open-ended problems to what Lynch et al. [19] called *Discovery Support Systems*. We redefine it to be about modeling/capturing the aspects of the problem space explored by the learner(s) so far - and how the course of that exploration has unfolded so as to have exposed aspects of the problem space to the learner.

There has been considerable research on design and impact of feedback in both ill-defined tasks and problems (E.g [4, 8, 11, 26, 9]) with methods like partial task models and in well-defined ([16, 7]) tasks and problems with model-based, constraint-based and expert solution-based approaches (See Lynch et al. [19], Fournier-Viger et al. [9] for extensive review). However, these studies have designed feedback by constraining some aspects of the open-ended problem making it less open-ended [9] and have reported findings and issues related to feedback design as very complex and often mixed [19]).

The purpose of our proposed data-driven formative feedback methods is to empower the learners themselves to reshape their exploratory path through the problem space such that it can be made more amenable for exposing learners to critical events, insights, and contrasts. These can range from simple evaluative feedback suggesting “correct” or “incorrect” where verifiable solutions are available, to complex elaborate maps illuminating the trajectory of exploration, or even tying the highlights of the exploration path with external concepts and theories. As an analogy - if prior methods of formative feedback are akin to giving a tourist step-by-step directions to reach a destination, we are attempting to produce an annotated map. We thus re-situate the problem-solving decision-making with the learners themselves, and see our mission as providing them with relevant, situationally-salient information to make those decisions.

We desire to give learners a sense of how their explorations map to the larger space of possibilities within the learning environment. In a truly open-ended learning environment, the space of possible action may be infinite, but there are often nonetheless common repeating patterns in action-response pairings. The more data we collect on how learners make use of a given learning environment, the better our map of the problem space - much like a travel guide that has been annotated by multiple tourists. To conceptualize what it means to provide a data-derived “annotated map” to learners in open-ended environments, we thus lean on the “fugue” construct developed by Reitman [28]. In music, a “fugue” is a short melody or phrase which is taken up by other instruments. We argue that data mining can be used to detect “fugues” developed by prior learners in response to certain situations within the problem space, “fugues” that could be presented to new learners as potential directions to pursue. Additionally, the “fugue” concept can be used to help learners reflect on their own exploration paths: are

they relying on very similar “melodies”, or branching out and trying new compositions? The value of the “fugue” concept is that it is not in contradiction with a multi-learner environment - the piece of music, as produced by the whole orchestra, is the subject of analysis.

2.1 Research Questions

We follow Reitman [28] recommendation of conceptualizing the problem solving in open-ended learning environments as “fugues” (like in music) where the learners could adopt a component solution and successively develop interweaving parts to that component of the solution. This leads us to:

RQ 1: What kinds of methods can be used to design domain-independent formative feedback to enable exploration and conceptualization of such “fugues”?

The idea of adopting problem solving in this manner implicitly includes metacognitive support (by providing learners with an exploration map of known “fugues”), and implicitly invites collaboration where the developmental work of one group can be picked up and further developed by others. We explore what features of the problem-solving would best motivate this kind of learning and how we could exploit these features through data-driven methods to design formative feedback.

RQ 2: How do these “fugues” of solutions repositories evolve as we expose more solutions? What limitations and advantages evolve as we expose more solutions?

As more and more groups attempt the problems the repository of known “fugues” expands, thus surfacing new possibilities for formative feedback and teaching methods in the existing domain like (1) a view into how learning, collaboration, innovation takes place in such ill-defined domain, (2) provide guidance for intervention by any humans-in-the-loop (e.g., educators), (3) use the repository to design context-specific (for learners directly) feedback for known actions/tasks, and motivate the design for similar domains by laying down foundations for (4) for the design of Intelligent Tutoring Systems which might not have a expert model readily available, and (5) for designing adaptive learning environments for ill-defined problems, where the problem can change difficulty level by tracking learners to have explored certain paths or length of paths. For my dissertation, I will explore the utility of formative feedback for the in-domain applications ((1)-(3)). However, the expansion of the “fugues” also references potential limitations of the methods, for example (1) the running time constraints for processing the data- a real-time formative feedback poses certain limitations on the time spent in processing the result which makes effectiveness rather than efficiency of the feedback a priority, (2) detecting and referencing the most commonly occurring “fugue” from/to the learners might potentially indicate tunnel vision, so helping the learners diversify “fugues” while preventing recursion problem must take precedence. Maintaining an effective balance to resolve these limitations would also be the scope of my dissertation.

RQ 3: What impact does the use of these “fugues” based formative feedback have on the learning opportunities in an open-ended learning environment?

We would like to measure the impact of the redefined formative feedback for open-ended learning environments designed in RQ 2 (with visitors and the educational staff) to validate our conceptualization and usefulness of formative “fugues” in aiding exploration and the effects of scaling on the formative feedback.

2.2 Case: Collaborative Open-Ended Simulation Based Museum Exhibit

We propose to design formative feedback for a mixed reality, simulation-based museum exhibit. Connected Worlds is an open-ended complex systems exhibit that can support up to 50 simultaneous users to explore and manipulate the ecosystem. Visitors interact with the simulation by diverting the flow of simulated water on the gallery floor, and by planting seeds in the biomes simulated on the wall projections. They are tasked with maintaining the diversity of four different biomes via planting and managing water resources. It serves as a good testing ground because the exhibit does not provide the learners with fixed goals or constraints for strategies encapsulating the two characteristics of open-ended learning environments: no verifiable solutions or end goals and no clear strategies to solve/ maintain the diversity. The visitors have to constantly work together to maintain the diversity and manage resources in the ecosystem, and there can be a varied different ways of doing the same, with interaction of the actions varying substantially across contexts nominally of the same type, producing different results across-context, a recognized quality of an open-ended task [33].

2.3 Preliminary Work and Future Directions

We have designed and built a system for unobtrusively collecting the “collective” interaction data while the visitors groups interact with the system and with each other, which is undergoing iterations to capture more facets of data. In prior work, Mallavarapu et al. [21] the data capturing system was validated by the use of a mobile interface to visualize the data for visitors, and the study showed that formative feedback influenced the problem-solving strategies the visitors were using. This study helped us establish the impact of formative feedback in an open-ended learning environment like our test site. In addition to the experimental and control contrasts in the above study we have collected interaction log-data from 32 school sessions which can be used for post-hoc processing, identification, validation of methods to design formative feedback. We propose a taxonomy of methods that can be used on the well-defined to ill-defined continuum to design formative feedback (See Table 1). Another work has recently used the school groups data to study and decipher the temporal cause-effect relationships between the learners’ collective interactions and the systemic responses [22]. This provided a conceptualization to the design of *Prediction based Feedback* (See Table 1). Our immediate future efforts will focus on applying and validating these methods with the current data in extracting and designing formative feedback for this environment. These methods will then be used through the mobile device to evaluate the impact on the exploration taking place in the exhibit.

3. ADVICE SOUGHT

1. What validation methods can be used to evaluate the methods that can extract the “fugues”? We acknowl-

Type of formative feedback	Information needed by recipient	Information needed by Analytics	Applicable analytic approaches	Applicable to "fugues"
Model based Feedback	Next steps to take, demonstration of a certain step, evaluation of skills and actions, Progress towards goals	"Goal" decomposition tree, Correct example(s), metric of correctness, task to action and skill mapping	Knowledge tracing map from goals to skills and tasks, expert models.	
Violation based Feedback	"Favourable" actions and "distance" from goals due to the action	Set of constraints on the "correct" behavior, Rules for task	Detecting when certain rule is violated.	
Sequence based Feedback (showing only ongoing interaction)	Solution paths, actions on the path	Definition of what constitutes a solution path, temporal order of <i>current</i> actions	Sequence mining where consequences of frequent previously seen sequences can be used as feedback.	X
Prediction based Feedback (showing only ongoing interaction)	Predicted Consequence of actions	Causal model of the learner interactions	Causal Inference, Regression.	X
Contrast based Feedback	examples that contrast on one or more dimensions of goals	Definition of dimension(s) of contrast and highlights for goals	Sequence mining, Ability to extract "Highlights", goals from interactions, clustering using defined dimensions of contrasts.	X
Trajectory based Feedback	A exploration map of path travelled placing them on continuum of paths	definition of dimension(s) of path characterizations, differentiating metrics	Sequence mining, Ability to extract/ differentiate trajectories, clustering.	X
Task/Events based Feedback	attempted tasks/ uncovered events on the trajectory	definitions of tasks and/ or events and their temporal order, definitions of trajectory	Ability to extract "tasks" from the actions, constituting them as trajectories, clustering depending on the definitions of tasks.	X
Comparison based Feedback	collection of trajectories attempted (till now)	definitions of trajectories, differentiating metrics	Ability to extract/ differentiate trajectories, clustering.	X

Table 1: Types of Formative feedback, information conveyed by them and details of the methods for the continuum of Learning Environments

edge that we are using the existing EDM methods to validate their applicability to our problem-space. We would want to evaluate each method for the same.

2. What other external factors need consideration when designing formative feedback for open-ended learning environments. For example, when designing formative feedback for problems tackled by individual learners researchers have explored the effect of individual differences [15, 34] on the impact of formative feedback through individual learner models; While evaluating the impact of formative feedback in collaborative open-ended learning environments - what factors do we need to consider?
3. Should we consider to establish a generalizability to this redefinition of formative feedback and its impact by validating our approach through another equivalent environment?

4. CONCLUSIONS

As we move from individually tackled well-defined problems to open-ended real-world problems to allow the 21st century learners to explore with their peers, we also need to make a move from "solution" based formative feedback to a more *Socratic* method [18] of providing feedback to enable explorations, thus giving the learners an opportunity to contemplate the implications of their decisions. Working synergistically with the learning environment the feedback should expose to the learners the opportunities to learn and practice abstract skills like reasoning, creativity, innovation, and encouraging the same in a collaborative environment. We identify the feedback for collaborative open-ended learning environments to have characteristics like meta-cognitive support, support for "collective" learner efforts, and be predicated on the characteristics of the problem space rather than the learner actions.

ABSTRACT

Determining when and whether to provide personalized support is a well-known challenge called the assistance dilemma. A core problem in solving the assistance dilemma is the need to discover when students are off-track or unproductive, so that the tutor can intervene. Such a task is particularly challenging for open-ended domains such as logic proofs, and programming. In this paper, we present a data-driven method to determine *step-level productivity* in a logic proof tutor. This approach leverages and modifies the Markov decision processes in the Hint Factory, a data-driven hint generator, to develop four productivity metrics. Our results provide evidence suggesting that, for each productivity metric, students' training productivity significantly correlates to their posttest performance. We conclude with a discussion outlining challenges posed when comparing these productivity metrics to a ground truth, and propose a preliminary approach to address them.

Keywords

productivity, open-ended, hint timing, assistance dilemma, logic proofs

1. INTRODUCTION

Intelligent Tutoring Systems (ITSs) provide individuals with adaptive feedback and hints, improving learning [25]. Studies suggest that hints, when provided appropriately, can augment students' learning experience [10, 22] and improve their performance [7]. However, researchers often find that students display poor help-seeking behavior [2, 21]; some abuse hints to expedite problem completion, and some avoid seeking help when they are in need [1, 20].

To deal with non-optimal help-seeking behavior, several ITSs provide unsolicited assistance [3, 18, 13]. However, determining *when* to provide proactive assistance, i.e., unsolicited

Mehak Maniktala, Tiffany Barnes and Min Chi "Extending the Hint Factory: Towards Modelling Productivity for Open-ended Problem-solving" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 796 - 801

assistance in anticipation of future struggle, is particularly challenging in open-ended domains where there are many possible correct solutions. The assistance dilemma is a well-recognized challenge in the domain of ITSs, where a trade-off exists between giving and withholding information to achieve optimal learning [14]. On one hand, providing assistance may reduce frustration and save students' time, but may lead to shallow learning or a lack of motivation to learn by oneself. On the other hand, withholding information can encourage students to learn by themselves, but may lead to frustration and wasted time [14, 16]. A core problem of the assistance dilemma is the need to discover when students are off-track or unproductive so that the tutor can intervene. We hypothesize that developing a proactive hint policy for a logic tutor, where tutor interventions are delivered upon predictions of unproductivity in training, can improve students' logic proof strategies in a posttest without hints.

Contributions. In this paper, we present our novel, data-driven approach to measure productivity in an open-ended logic ITS. We extend the Hint Factory [24], a generalizable data-driven method for hint generation, to define four metrics of productivity. We then present our preliminary analysis on evaluating these metrics in the logic tutor.

2. RELATED WORK

Several studies have used the term "unproductive" to refer to undesirable behavior during training [12, 9, 19]. For example, Beck and Gong [8] define unproductive persistence or "wheel-spinning" based on whether or not a student achieved mastery (three correct problems) in 10 problem attempts. Their definition of unproductivity has been used in recent studies to predict when an intervention can help students by distinguishing between productive and unproductive behavior using decision trees [12] and Recurrent Neural Networks [9]. However, this definition of problem-level and problem-completeness based productivity is not suitable for our objective of guiding students toward efficient problem-solving strategies at a finer step-level granularity, specifically in open-ended domains.

McLaren et al. in a study on an open-ended inquiry-learning program defined unproductive events as the actions taken by the student that do not help them achieve the goal of a particular level, i.e., the steps that students take that are unlikely to advance their understanding of the concepts being taught [16]. Similar to this study, we define productivity on a step level to identify student steps that are not likely

to advance their problem-solving strategies. However, our definition is different in that we did not use a pre-defined domain-specific metric for efficient and inefficient strategies; rather we focused on solution length or optimality, which is valued across problem-solving domains.

In many multi-step open-ended but well-structured problem-solving domains, shorter solutions are considered to be more optimal than longer ones, and solving problems in less time reflects both learning and fluency [15, 23, 26, 11]. We use these basic assumptions about time and solution length to design a data-driven, domain-agnostic approach to model productivity on problem-solving steps. The Hint Factory is a data-driven approach for hint generation. The approach uses prior students' transaction log data to form an interaction network and assign scores to problem-solving states (snapshots of an on-going or completed proof) [24, 5]. A core insight of the work in this paper is that we can similarly use interaction networks to score productive problem-solving steps without the need to model the domain.

3. METHOD & PRELIMINARY RESULTS

In this section, we define *productivity*, a data-driven measure quantifying how much a student's most recent step contributes to an efficient solution. We explore four new productivity metrics defined using the combination of the *quality* of each state (local or global), and the amount of *progress* made in a step (absolute or relative). First, we present the Hint Factory. Next, we present our extension of the Hint Factory, and how we use it to define productivity.

3.1 Hint Factory

Hint Factory is a method for generating hints in multi-step open-ended domains [6]. In the Hint Factory, historical student solutions are used to form Markov decision processes (MDP) from interaction networks, where vertices are observed student problem-solving states (snapshots of their on-going or completed proof), and edges are problem-solving steps, i.e., a transition between states. The Hint Factory uses value iteration, a reinforcement learning technique, given in Equation 1, to assign an *expected value* $LQV(s)$ to each state s , where $LR(s)$ is the state's reward, γ is the discount factor, and $P_a(s, s')$ is the proportion of the observed solutions in state s that lead to state s' using the action (i.e. step) a . In the Hint Factory, a large reward is set for the problem-completion or *goal states* (100), penalties for incorrect states (10), and a cost for taking each action (1) [5]. A non-zero cost on actions causes the MDP to penalize longer solutions.

$$LQV(s) := LR(s) + \gamma \max_a \sum_{s'} P_a(s, s') LQV(s') \quad (1)$$

3.2 State Quality - Extending the Hint Factory metrics

In this section, we leverage the Hint Factory approach to generate two quality metrics that determine the expected values for each observed problem-solving state. The first metric of state quality was defined as part of our prior work on the Hint Factory, which we label as *local quality*. Local quality provides insights about how far a state is from the closest goal state, weighted by the probabilities of transitions, but it cannot provide information about whether the state is on an efficient path to a solution.

$$GQV(s) := GR(s) + \gamma \sum_{s'} P_a(s, s') GQV(s') \quad (2)$$

Global Quality. We devised a novel, data-driven global quality value function, GQV in Equation 2, to give higher values to states on efficient solution paths. Equation 2 sums $GQV(s')$ over all states s' reachable from s , weighted by $P_a(s, s')$, taking into account all future actions from a current state, rather than just the one with the max expected value. The global rewards GR are identical to LR for errors and actions, but are different for goals, giving shorter, more efficient solutions higher rewards. The global reward $GR(g)$ for each goal state g on a problem is $GR(g) = 100 - p * \delta(g)$ where $\delta(g)$ is the difference between the solution length of g and that of the shortest solution, and p is a penalty for longer solutions. We set $p = (100 - 80) / \delta_{median}$ where δ_{median} is the difference between the median and shortest solution lengths for each problem because median student solution lengths are assigned a global reward of 80. Meaning, the student's performance with a median solution length represents a low B grade. The proof of convergence for the modified value iteration equation 2 is given in appendix A.

We now demonstrate the differences between local and global quality metrics using solution trajectories (series of steps) of varying solution lengths: T_{short} , T_{medium} , and T_{long} in Figures 1 and 2. T_{short} is the shortest solution (four steps), with all nodes (logic statements) used. Note that a node is said to be *used* if it contributes towards deriving the conclusion of the problem. T_{medium} has five steps with one unused node D ; and T_{long} has eight steps, and all nodes used.

We generated interaction networks to determine the quality values for each problem using our historical data for $N = 796$ students. Figure 2 shows the quality values for the three trajectories in Figure 1. The start state in Figure 2 consists of the three given logic statements (the topmost state). Arrows between states represent steps, i.e., transition between states by logic rules applications. Non-start states are represented by a $+(XYZ)$, where XYZ is the new logic statement derived in a step. The start state has a high global quality, but low local quality. The start state's global quality is high because all efficient paths contain it, but its local quality is low because it is probabilistically farther away from goals than any other state in the figure. The local quality for states that are only found in incomplete attempts is lower than that for the start state. The local quality of the goal states on all three trajectories is 100. The global quality value for the goal state in each solution trajectory differs, with 100 for the T_{short} goal (since it's the most efficient), 95 for T_{medium} , and 80 for T_{long} goal states.

From the start state to the goal in T_{short} , both local and global quality state values increase monotonically since it is the most efficient solution. Note that not all quality values increase over every trajectory. For example, step $T_{medium} - 2$'s pre-state $(+A \rightarrow E)$ global quality is higher than that for its post-state $(+D)$ since the pre-state is on a more efficient path, but the local quality increases from pre- to post-state. Step $T_{long} - 3$'s pre-state $(+\neg E)$ has higher local and global quality values than its post-state $(+\neg E \rightarrow \neg A)$ since the post-state is farther from and less likely to reach T_{long} 's

Figure 1: Three Solutions with Varying Number of Steps for a logic problem in Deep Thought

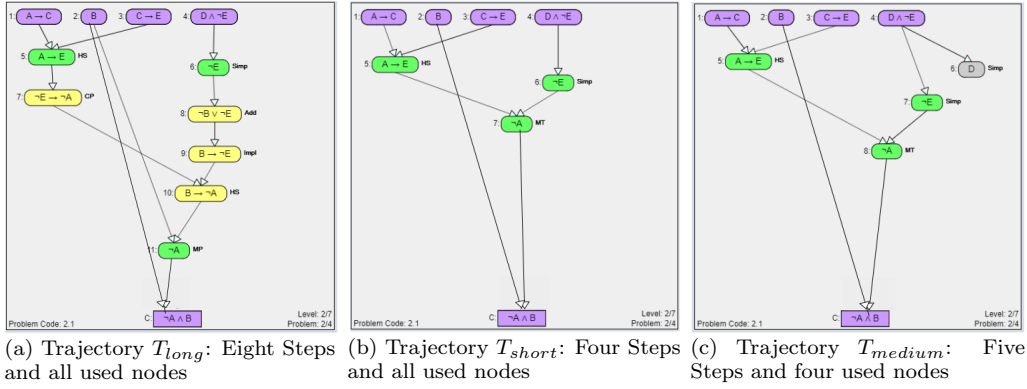

Figure 2: Illustration for the concepts of State Quality and Productive steps in 3 trajectories T_{short} , T_{medium} , and T_{long}

goal than the pre-state is to T_{short} 's closer goal. The global quality decreases for two reasons: (1) T_{long} goal is on a less efficient path, and (2) global quality performs a weighted sum over all the subsequent, previously-observed states in the larger (unshown) interaction network, many of which lead to incomplete attempts.

These examples demonstrate the differences between local and global state quality metrics. The main strength of generating these quality values is the MDP approach which ensures that each state quality value is based not only on the distance from a solution but also on the probability of transition at each of the successive steps. This allows us to rate steps in a more probabilistic manner than a simplistic comparison based on the distance from the most efficient expert solution.

3.3 Progress - Change in Quality

Since state quality is a measure of relative "goodness", we compare the quality of the current state with that of the previous and start states to evaluate the productivity in a step. In this section, we define two measures for *progress*: *relative*, the change in state quality from the *previous* problem-state, and *absolute*, the change in state quality from the *start*.

Relative progress is the difference between the quality values of the current and previous states. Relative progress with local quality identifies whether the previous or current state is closer to the goal. When using the global quality values, the relative progress identifies the state closer to a goal, and provides additional information detailing which one of the two is on a more efficient solution path.

Consider a valid, but long solution attempt. A relative progress measure reveals whether a student is progressing toward a solution in a step, but not whether their trajec-

Quality-Progress	Productivity Formula
Global-Absolute	$(GQV_{post-state} - GQV_{start-state}) \geq 0$
Global-Relative	$(GQV_{post-state} - GQV_{pre-state}) \geq 0$
Local-Absolute	$(LQV_{post-state} - LQV_{start-state}) \geq 0$
Local-Relative	$(LQV_{post-state} - LQV_{pre-state}) \geq 0$

Table 1: Step Productivity formula based on state Quality values and step Progress

tory is efficient. Therefore, we define *absolute progress* as the difference between the current and start states' quality, using either quality measure. Absolute progress using local quality reveals whether a student's current state is farther or closer from any goal states than when they began working on the proof. Global quality based absolute progress reveals the amount of efficient progress a student has made between the start and the goal. For example, if we compare the absolute progress on two consecutive steps of a solution attempt, if a student is taking efficient steps, then the absolute progress will increase on every step.

3.4 Productivity - Quality & Progress

We define four kinds of productivity measures based on quality {Local, Global} and progress {Relative, Absolute}. A step is considered *productive* if the progress of its post-state using either quality measure is a non-negative number, and *unproductive* otherwise, as shown in Table 1.

In consultation with an expert who has more than twenty years of experience teaching discrete math, we labeled the steps as productive or not in each of the three trajectories ($T_{short}, T_{medium}, T_{long}$) shown in Figure 1. Expert-assigned unproductive steps in Figure 2 are displayed in red and others are in green. According to the local quality and absolute progress (local-absolute) productivity metric, all the steps are productive because they eventually lead to a solution. However, this metric is not sensitive to variations in the solution lengths. When we use local-relative productivity, only the $T_{long} - 3$ step is unproductive, as it is the only step where a post-state is probabilistically farther from a solution than the pre-state. Using the global-relative measure, steps $T_{medium} - 2$ and $T_{long} - 3$ are unproductive because they have a pre-state on a more efficient path to the solution than the post-state. The global-absolute metric is the only measure that labels the four expert-identified unproductive steps correctly.¹ Note that each type of productivity captures a different perspective on a step towards the solution. Overall, the global-absolute productivity metric aligns perfectly with the expert's labels for the sample trajectories. However, using a panel of experts to rate each step would provide a more robust assessment of the ground truth. A major challenge in a manual inspection by a panel of experts is our vast state-space ($N = 72,560$).

3.5 Selecting a Productivity Metric

¹Note that these four unproductive states also correspond to the four infrequently used (yellow) nodes in the student solution shown in Figure 1a. However, some unproductive nodes have been observed to be frequently used, and some productive nodes to be infrequently used in our tutor, suggesting that the use-frequency alone cannot determine productivity

Productivity Using	Corr
Global-Absolute	0.328
Global-Relative	0.261
Local-Absolute	0.294
Local-Relative	0.236

Table 2: Correlation between students' Training Productivity and Posttest Optimality (all correlations are significant with $p < 0.01$)

To understand which one of the four productivity metrics is most indicative of how students' work in the tutor's training section affects their posttest solution optimality, we conducted a correlation test. Note, we evaluate students on an *optimality* score, which is as an exponential decay function on normalized steps e^{-steps} to account for the small variance in the number of steps. Steps are normalized to the interquartile range for each specific problem to account for varying lengths/difficulties. Very short solutions with step count less than or equal to Q1 (first quartile) have, *optimality* = 1, and those with step count greater than Q3 (third quartile) have an optimality score of 0.36 or less based on the exponential decay curve.

For each student in our dataset ($N = 437$), we computed their posttest optimality and the proportion of training steps that are productive using each productivity metric. We then calculated the correlation between each type of training productivity with posttest optimality using Pearson's coefficient. Table 2 shows that higher productivity in training is significantly correlated to better posttest optimality for all the productivity metrics. Among them, the global-absolute metric is the most correlated with posttest optimality.

4. CONCLUSION & ADVICE SOUGHT

In this paper, we provide a unique extension of the Hint Factory to determine productivity on a step-level in a logic ITS. Outside the scope of this paper, we assessed the impact of intervening with hints using a predictor of unproductivity (global-absolute) in a controlled study with two conditions: control and adaptive. Students in both conditions could request hints, but interventions using the predictor were given only in the adaptive condition. We found that the adaptive condition students had significantly better posttest optimality and time than their control peers. Our long term aim is to assess the generalizability of this approach in other open-ended domains such as programming, and to address the assistance dilemma for open-ended problem-solving.

For this doctoral consortium, we would like advice on how to further assess and compare the productivity metrics against a ground truth. We plan to form a panel of experts to rate a larger number of steps, but it is infeasible for them to rate each step in our vast state-space. Do we employ data-driven methods to determine the ground truth? I would like to discuss data-driven ways to evaluate the productivity metrics such as using inferring rewards from Gaussian processes [4] or using procedural solution generators [17].

Our preliminary results are promising, and through this consortium, we seek to determine a method to assess the ground truth of step-level productivity in the logic tutor.

APPENDIX

A. PROOF OF CONVERGENCE FOR THE MODIFIED BELLMAN BACKUP FUNCTION

Theorem: The modified Value iteration (Eqn 2) converges to GQV^* for any initial estimate GQV , i.e.,

$$\lim_{k \rightarrow \infty} GQV_k = GQV^* \quad \forall GQV$$

For any estimate of the value function GQV , we define the modified Bellman backup operator $\hat{B} : R^{|S|} \rightarrow R^{|S|}$

$$\hat{B}GQV(s) = GR(s) + \gamma \sum_{s' \in S} P_a(s, s') GQV(s')$$

Before we provide the proof of convergence, we provide the proof of contraction, i.e, for any two value functions GQV and GQV' :

$$\|\hat{B}GQV_k - \hat{B}GQV'_k\| \leq \gamma \|GQV_k - GQV'_k\|$$

where the max norm:

$$\|GQV\| = \max_{s \in S} |GQV(s)|$$

$\|v - v'\|$ = Infinity norm (max difference over all states)

Proof of contraction:

$$\|\hat{B}GQV - \hat{B}GQV'\|$$

$$= \left\| \left[GR(s) + \gamma \sum_{s' \in S} P_a(s, s') GQV(s') \right] - \left[GR(s) + \gamma \sum_{s' \in S} P_{a'}(s, s') GQV'(s') \right] \right\|$$

$$= \gamma \left\| \left[\sum_{s' \in S} P_a(s, s') GQV(s') - \sum_{s' \in S} P_{a'}(s, s') GQV'(s') \right] \right\|$$

$$= \gamma \left\| \left[\sum_{s' \in S} P_a(s, s') (GQV(s') - GQV'(s')) \right] \right\|$$

$$\leq \gamma \max_s \sum_{s' \in S} P_a(s, s') |GQV(s') - GQV'(s')|$$

$$\leq \gamma \sum_{s' \in S} P_a(s, s') \|GQV - GQV'\|$$

$$= \gamma \|GQV - GQV'\|$$

since $P_a(s, s')$ are non-negative and sum to one

Proof of Convergence:

$$\begin{aligned} & \|GQV_{k+1} - GQV^*\|_\infty \\ &= \left\| \hat{B}GQV_k - GQV^* \right\|_\infty \\ &\leq \gamma \|GQV_k - GQV^*\|_\infty \leq \dots \\ &\leq \gamma^{k+1} \|GQV_0 - GQV^*\|_\infty \rightarrow 0 \end{aligned}$$

Scalability in Online Computer Programming Education: Automated Techniques for Feedback, Evaluation and Equity

ABSTRACT

The delivery of programming courses online offers great promise to provide quality programming education in an accessible manner. However, it also introduces new challenges, including how to maintain course quality as the ratio of students to teaching staff increases. In particular, the provision of effective feedback, detailed course evaluations and the promotion of equity can all become more challenging as the size of a course increases. This work explores, integrates and develops potential data mining and artificial intelligence techniques that could be utilised to address these issues in the context of programming education.

Keywords

programming education, automated feedback, course evaluation, equity, computer science education, student behaviour

1. INTRODUCTION

In recent decades, online programming courses have become increasingly numerous, with a diverse range of languages being taught on a variety of platforms. Due to their online nature, these courses are highly accessible and available to a large number of students. In addition, they do not require teachers and students to be in close proximity, making them more robust to disruptions from global events, such as the COVID19 pandemic [1]. Considering these benefits, methods for increasing the effectiveness of these courses are of great significance, with the potential to benefit many thousands of students.

One important challenge in educational settings is ensuring there is effective information flow between teachers and students. In particular, there should firstly be a way for instruction and feedback to flow from teachers to students so that students can learn. In addition, there should also be a way for information about student understanding and progress to flow from students to teachers so that teachers can adapt and improve the instruction and feedback (re-

ferred to as “closing the loop” [3]). This challenge becomes increasingly significant in the context of online education, where teachers and students may not be in direct contact and there may be a large number of students per teacher.

Some approaches to improving information flow in online education have focused on opening communication channels between teachers and students. For example, discussion boards [16], one-on-one chats with tutors [7] and student surveys [17] all allow teachers to provide instruction to or receive feedback from students. One issue with these approaches, however, is that they can suffer from scalability issues. For example, as the ratio of students to teachers increases, it becomes more difficult for teachers to monitor every discussion board question, to engage in every chat or to carefully read all open-ended survey responses. In addition, approaches to dealing with this, such as making surveys quantitative, can limit the detail of the feedback.

Since direct communication channels for closing the loop can suffer from scalability issues, another approach is to introduce automated systems as interfaces between teachers and students. In particular, teachers can configure an automated system for providing instruction and feedback to students, thereby allowing information to flow from teachers to students. In addition, automated systems can be used to analyse student behaviour and report back information about student progress to teachers, which they can use to re-configure the system, forming a loop as shown in Figure 1. This model can then be extended to consider additional loops, such as between students and the feedback system. Such systems are a highly promising approach to providing scalable education to students.

This work focuses on addressing a few key challenges associated with this approach that are both particularly important in the context of programming education and also less developed in the field at large. In particular, it first considers automated feedback techniques, and how these can be integrated together to gain a coherent picture of the current state of the field. In addition, it develops new EDM techniques for analysing student behaviour in order to evaluate a course generally, and also in the context of equity. As such, this work acts as a step towards improving the scalability and effectiveness of online programming education.

2. CONTRIBUTIONS

2.1 HINTS: A Framework for Automated Hints

Jessica McBroom, Kalina Yacef and Irena Koprinska "Scalability in Online Computer Programming Education: Automated Techniques for Feedback, Evaluation and Equity" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 802 - 805

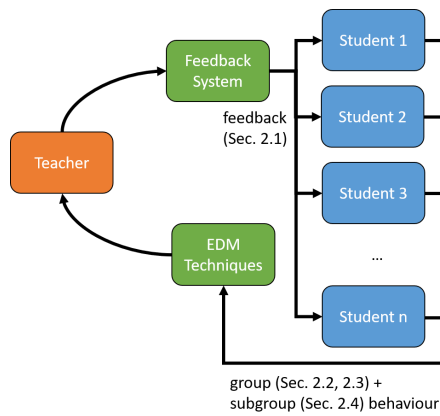

Figure 1: An example of scalable information flow between teachers and students. First, the teacher configures a system to provide automated feedback to students. Then, EDM techniques are used to analyse the behaviour of students and inform the teacher of their progress, thereby “closing the loop”. The teacher can then make improvements to the system based on this information. The section labels indicate how the work described in the next section relates to this model.

When undertaking a programming course, students are often presented with various programming exercises to complete in order to gain practical experience. Since students commonly find these tasks challenging, an important component of an automated feedback system is the ability to provide hints to students experiencing difficulty on programming tasks. Such hints could include suggestions about where the student went wrong, how to proceed or concepts to revise.

A wide range of interesting techniques have been developed to provide automated hints to students, including hints that use data from peers, model solutions and test cases and utilise a diverse range of methods to produce hints, including neural networks [2], Markov Decision Processes [15], program synthesis techniques [6] and a variety of other approaches [4, 5, 13]. In addition, systems employing automated hint techniques differ with respect to the programming language taught, evaluation method, student cohort and learning context. While this diversity offers great promise for producing high quality hints and represents the great interest in the area, it also increases the difficulty of understanding the types of techniques that are available and how they fit together.

The first contribution of this work, described in detail in [9], is a framework and survey to draw these techniques together into a coherent picture. In particular, the contribution is the *Hint Iteration by Narrow-down and Transformation Steps* (HINTS) framework. This framework focuses on understanding hint techniques by decomposing the process they use to produce hints into a series of smaller steps, which can then be fit into two categories: narrow-down and transformation steps. For example, in [14] the first step is to find the closest solution to a student’s program, and the second step is to then find edits from the student’s program to that solution. Once hint techniques are considered as a series of smaller steps, it becomes much easier to relate techniques

based on their steps to see how they fit together and the potential avenues for further developing them.

A summary of the five most important insights gained by surveying automated hint techniques in this manner are as follows:

1. Even if hint techniques appear very different overall, they can be related together by their smaller steps. This allows, for example, for them to be collected together into a single diagram to provide a coherent picture of the current state of hint techniques.
2. It is important to consider individual steps of hint techniques when evaluating, discussing and developing hint techniques, since these can often be mixed and matched.
3. there appears to be a theoretically motivated relationship between some hint technique steps and data-driven evaluation techniques, which would be interesting to explore further
4. The question of why hint techniques can be fit together in this way provides insight into the nature of automated hint generation. In particular, the fact that hint techniques can be decomposed into a series of smaller steps that fit into only two simple categories suggests this structure may be necessitated by the problem in general.
5. Further work on hint technique evaluation methods is necessary - there are so many possible combinations of steps that the efficiency of evaluation techniques must be improved.

Since understanding the types of hint techniques that are available and how they fit together is an important step in developing and evaluating automated feedback systems, this work contributes to improving such systems, which are an important component of scalable programming education.

2.2 A Technique for Clustering Student Programs

An important aspect of understanding student learning in a programming course is the ability to visualise the behaviour of students on programming exercises. In particular, understanding how beginner students behave during the first few exercises is of particular importance, since these students are more likely to make many mistakes, be least equipped to correct these mistakes and potentially be discouraged from the area if they experience too much difficulty.

The second contribution of this work is a technique for clustering beginner student programs in order to visualise trends in student behaviour when completing programming tasks. This technique, described in more detail in [12], involves first applying transformations to group logically equivalent programs. The resulting groups are then further combined if the structures of the programs in the groups are the same up to a customisable threshold and they pass the same test cases. In this way, programs with a similar functionality are clustered together, and it is possible to understand all possible programs in a cluster using a single sample program from the cluster.

After the clustering is performed, the clusters can be organised into a network with edges showing how students transition between clusters as they work on an exercise. Sequential pattern mining can also be performed to discover the most frequent transitions. This can then reveal information about where students experience difficulty (indicated by loops in the network) and the strategies they follow to complete an exercise. Example applications are also discussed in [12].

Planned extensions of this work include a more thorough evaluation beyond the case study in [12], and also an exploration of this technique in the context of equity, as discussed in Section 2.4.

2.3 DETECT: A General Clustering Technique for Temporal Trends in Student Behaviour

Many EDM techniques utilise clustering to understand student behaviour since clustering can condense highly complex information into simpler and more manageable subsets. This can allow the results to be more easily interpreted and thereby provide greater insight into student behaviour. However, while existing techniques can be readily applied to discover different types of student behaviour, it can often be more challenging to use them to discover particular behavioural trends in time. This is because the objective functions they use, which guide the cluster formation, often do not consider temporal information.

The third contribution of this work is DETECT (*Detection of Educational Trends Elicited by Clustering Time-series data*), a customisable hierarchical clustering algorithm for detecting trends in student behaviour over time. This algorithm, described in detail in [11], produces clusters similar in structure to a decision tree, with clusters defined by decision rules (e.g. a cluster may be all examples where the time taken was ≤ 5 mins and the student's grade was A). To form these clusters, DETECT uses a customisable objective function, which governs the types of temporal trends that are found. For example, these could include behavioural changes between the start and end of a course, or behaviours that make an exercise stand out from the ones before and after it. The algorithm then works by recursively dividing the examples into subsets in the manner that maximises the objective function.

Some advantages of DETECT in an educational context are as follows:

1. It is applicable to a wide range of educational datasets. A core feature of educational courses is that they tend to have a repeating structure. For example, they may have a series of lectures, homework tasks, assignments, tutorials, readings or practice exercises, which each have a similar structure. As such, these courses can be divided into time steps with similar features, which is the type of data DETECT is applicable to. For example, time steps could be homework tasks and features could include the time taken and grade. This allows DETECT to be applied to a wide range of educational data set, including programming data.
2. The objective function is customisable and has few constraints. In [11], two different objective function examples are given: one for finding differences between

the start and end of a course, and one for finding behaviours that characterise a particular exercise. However, this function can be customised to find other types of trends with minimal constraints (e.g. the function doesn't need to be differentiable). This allows DETECT to be highly flexible.

3. The results are easy to interpret. Since the clusters are defined by decision rules, it is easy to understand exactly which examples belong to each cluster, thereby improving the interpretability of the results
4. The algorithm is more robust to dependencies between features than traditional clustering methods, since the objective function can use temporal information to evaluate cluster quality. In particular, DETECT places higher weight on features that reveal interesting trends in time beyond what has already been found. As such, highly correlated features are penalised, making DETECT more robust to dependencies between features.

Planned extensions of this work include a deeper exploration into potential objective functions beyond the two discussed in [11] and a more thorough evaluation of the algorithm.

2.4 Adapting Techniques to Explore Equity Issues

One important issue when applying data mining techniques to student data is that patterns from under-represented groups can sometimes be obscured by collective trends. For example, if clustering is used to find the general types of student behaviour overall, this may obscure the potentially unique behaviour of subgroups, especially if they are small. As such, an important aspect of closing the loop between teachers and students is ensuring that analysis techniques not only provide information about the majority of students, but also minority groups.

The fourth contribution of this work is an exploration of equity issues in the context of programming education, and how the proposed techniques might be adapted to provide information about under-represented student groups. This work is still in progress, but so far has included:

1. an exploration of gender differences in enrolment and exercise completion rates in a series of programming courses, described in [10]. In particular, the courses were run for school students during a 5 week Python programming challenge in Australia in 2018, and included both block-based and text-based courses of different difficulty levels. In general, there were approximately twice as many male enrolments as female, but little difference in exercise completion rates between genders. Such an analysis acts not only as an important first step in understanding the nature of student differences in a course, but also as a baseline with which to compare data mining techniques
2. adapting DETECT to consider gender and school grade differences among students in the lead up to them dropping out. [8] In particular, this involved selecting 10 evenly spaced out programming exercises for each student who dropped out (i.e. the first exercise they completed, the last exercise they completed and

8 equally spaced out exercises in between). These exercises could then be used as time periods that were relative to the students (i.e. time 1 was when he student first began, time 2 was 10% of the way through their interaction with the course, and time 10 was the last exercise they completed before dropping out). DETECT could then be applied to this data to see the largest changes in student behaviour approaching dropping out, which could then be filtered based on gender and school grade to observe differences in the lead up to dropout for different groups.

Planned extensions to this work include adapting the program clustering technique from Section 2.2 to consider equity, and to extend the analyses by considering data from consecutive years.

3. CONCLUSION

In the context of programming education, one approach to increasing information flow between teachers and students in a scalable manner is to introduce automated systems as interfaces between teachers and students. This work aims to address a few key theoretical challenges in working towards this, with a focus on the automated techniques necessitated by such an approach. In particular, it presents a framework for integrating automated programming hint techniques, two clustering techniques for analysing student behaviour and an exploration of how such techniques can be adapted to investigate equity issues. As such, it acts as a step towards increasing information flow between teachers and students in a scalable manner, with the ultimate aim of improving programming education.

4. ADVICE SOUGHT

Any general feedback on this work, including its contributions and the problems it addresses would be most welcome, particularly in the context of thesis writing. Additionally, any suggestions for improving the coherence or completeness of the work, or other ideas for improvement would be of great value. For context, this work has been conducted over 2.5 years of PhD study, with up to 1.5 years remaining.

ABSTRACT

Due to the increasing interest in the online learning environment, particularly in Massive Open Online Courses (MOOCs), predictions and education data mining have rapidly gained prominence in education studies over the past decade. The massive amount of student data available in MOOC platforms enables us to gain insight into students' learning behaviours. Therefore, this paper outlines the doctoral work that explores the idea of 'student roles' and their linguistic changes to analyse the students' learning behaviours in MOOCs. A multi-class classifier has been built to identify user roles (e.g. information seeker, information giver) with 82.30% F-measure. Preliminary results on linguistic experiments demonstrate, distinguish linguistic behaviours can be observed in different user roles. The outcome of this research study will contribute to a learning model that can be used to understand students' learning process.

Keywords

MOOCs, Discussion forums, User Role, Natural Language Processing, Machine Learning.

1. INTRODUCTION

Learning Analytics has been gaining high popularity in recent years among research scholars due to the challenges it imposes; two of which are increasingly complex, large-volume data and heterogeneous data. Integrating several sources of data that are generated during learning activities is of major need for the education sector to provide timely enhanced services to both students and instructors. Integrating and analysing student data can contribute immensely towards reducing dropout rates, timely instructor interventions, and many other [4].

In the 21st century, students are more exposed to Massive Open Online Courses (MOOCs) and online learning environments as they believe it is more beneficial than the traditional learning environment such as flexible study hours, availability for everyone [7]. As many of the MOOCs are freely available for students, it draws the interest of thousands of learners. However, accessing the success rate of a student learning in online platforms has become difficult as students enrol for varying purposes. Knowing that students may enrol in courses for other purposes, we need to explore other perspectives of learning success beyond

completion.

MOOC contains many types of resources to support students in their learning activities. These elements can be categorised as videos, lecture series, reading materials, quizzes, assignments, discussion forums etc. According to Anderson [1], discourse enables the learner to come up with their own reasoning and logical thinking by communicating with others. Thus, investigating discussion forums will help researchers to understand the actual situation of the students in the learning lifecycle.

The overarching aim of this doctoral work is to understand students' learning with time within MOOCs. To this end, the research mainly focuses on examining user role transformation and linguistic change that occurs in discussion forums with time. We believe analysing these roles and associated linguistic changes will eventually result in a deeper understanding of the student's learning lifecycle. Further, this research will also investigate the influencing factors (e.g. course structure, learners' demographic) that influence these observable features (i.e. student role, linguistic expression) and their correlations.

To achieve the aforementioned aim, our investigations are driven by two main research questions (RQ):

RQ 1: Can student role and linguistic expressions be used to understand student learning? (1. How to build a predictive model that predicts students' roles in an online learning environment? 2. How to track the linguistic change of each student roles in the online learning environment?).

RQ 2: To what extent students' learning is affected by external factors? (1. What are the external factors that affect these transformations (user role and linguistic change)? 2. What are the correlations between external factors and these transformations?).

The contribution of this doctoral work includes a predictive model that leverages linguistic-only features to predict student roles in discussion forums. Further, this doctoral work develops a linguistic framework to understand students' learning. This demonstrates distinguish linguistic behaviours of different student clusters in discussion forums. Moreover, identifying the external factors such as course structure, learners' demographic that affect students' learning and their correlation.

2. RELATED WORK

2.1 Post classification and role identification in discussion forums

User role classification is grounded by post-classification methodologies that prevail in the existing literature. In other words, post-classification is the foremost step that needs to be carried out in order to identify the user roles in discussion forums. With the examinations on speech acts by Searle [9], there are

Lavendini Sivaneasharajah, Katrina Falkner and Thushari Atapattu "Investigating Students' Learning in Online Learning Environment" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 806 - 809

several post-classification methodologies have been introduced to the research community.

While prior studies classify forum posts into different categories such as question, answer, solutions, Hecking et al. [6] have carried out post-classification by generalising the categories that prevail in the existing studies [2]. The study presents three different classes namely: information seeking, information giving and other. Hecking et al. [6] achieved 70% accuracy using content-related features (e.g. phrases – “need help or helps you”) and contextual features (e.g. position in the thread, number of votes) for classification purposes. However, relying on contextual features for forecasting is not feasible in a real-time system as these contextual features changes with time. And predictions can only be made at the end of the course as they occur during the course. Therefore, our study aims to build a predictive model for discussion forum classification using linguistic-only features while eliminating contextual and structural features.

2.2 Linguistic change in online communities

For decades, researchers in the linguistic discipline have explored the language change in many different spheres starting from historical linguistics to sociolinguistic. Research scholars believe exploring temporal changes in user’s language will provide useful insights to research communities. Linguistic research has taken various paths with time to exhibit correlations between the linguistic and other aspects such as historical change, community norms, user lifespan etc.

The work by Nguyen et al. [8] identifies the relationship between community membership and language use. According to their findings, forum specific jargons and informal linguistic style can be observed in long-term participants’ discourse. Dowell et al. [5] have conducted a study on MOOC data to identify the conversion in learner’s language and discourse characteristic with time. However, the research did not investigate the linguistic changes associated with each user role. It is said that learner’s language changes with time, especially discourse in discussions forums will be topic-oriented and reflective of deep learning with the consequent offerings of a course [5]. Nevertheless, investigating linguistic change for a student role has not been addressed. Even though preliminary work on linguistic change has been conducted in other online communities, there is a lack of work conducted in MOOCs.

3. METHODOLOGY

This doctoral work will be conducted in two main phases namely:

1. Pilot study - Identifying potential features from discussion forums.
2. Building machine learning model - Implementing a model to understand student learning. The phase two will be further divided into three sub tasks to address aforementioned research questions as follows:

Task 1: Developing predictive model to identify user roles (IG/IS and O) in discussion forums.

Task 2: Developing a machine learning model to track linguistic change.

Task 3: Identifying external factors and their correlations with user roles and linguistic expressions.

4. EXPERIMENTS AND RESULTS

The study collected 9,497 user posts from 923 users from the AdelaideX¹ ‘Introduction to Project Management’ and ‘Risk Management for Projects’ courses offered in 2016 and 2017 respectively. The current study was conducted using 6000 posts from ‘Introduction to Project Management’. Two independent human evaluators carried out a manual annotation with a high inter-rater agreement (Cohen’s kappa = 0.925) and annotated the user posts as information seeker (IS), information giver (IG) and other (O).

4.1 How to build a predictive model that predicts students’ roles in an online learning environment? (RQ1)

A multi-class classifier was built to predict user roles (IG, IS and O) for a given forum post using discourse features and linguistic features. The features were extracted using Pennebaker’s Linguistic Inquiry and Word Count (LIWC) tool² which generates different linguistic measures for an input text. The study selected sixteen optimal features using Recursive Feature Elimination with Cross-Validation feature selection technique.

We implemented following multiclass classifiers with different sets of algorithms using Weka: Naïve Bayes, Random Forest, Simple Logistic Regression, Logistic Regression and Sequential Minimal Optimisation (SMO). All these classifiers were tested using 10 Fold Cross-Validation to assess the accuracy. Among these, the Random Forest classification model performed best with 82.30 of F measure.

Further, we also fine-tuned the parameters for Random Forest classifier using the scikit-learn library (RandomizedSearchCV and GridSearchCV). The results show that Random Forest classifier performs at its best in the following parameter setting: n_estimators:400, ‘min_samples_split’:10, ‘min_samples_leaf’: 4 and max_depth: 70.

Table 1: Results of classifier performance

Classifiers	Accuracy	Precision	Recall	F1	Cohen’s Kappa
Naïve Bayes	71.28	74.40	71.30	71.00	0.5117
Random Forest	82.17	82.30	82.20	82.20	0.6955
Simple Logistic	79.35	79.60	79.40	79.40	0.6473
Logistic	79.43	79.70	79.40	79.50	0.6498
SMO	74.80	76.50	74.80	75.30	0.5770

The work by Hecking et al. [6] is the only existing work in our workspace that classify the discussion forums posts as information giving, information seeking and other. They have achieved an overall of 71.5 F-measure for IS and IG class while obtained an average of 70 and 66 for precision and recall respectively across all three classes. With 82.30% of F-measure, we have demonstrated that analysing the language of post content itself is sufficient to predict user roles. Therefore, it is evident that linguistic features have a high impact on user role prediction in discussion forums.

4.2 How to track the linguistic change of each student roles in the online learning environment?

An important component of this research study is to propose a linguistic framework that can exhibit the linguistic characteristic of different student clusters that will be identified by this study. Afterwards tracking their changes associated with each student role. To achieve this, we carried out linguistic experiments to identify distinguishing characteristics between these student roles.

We started with a simple word count and performed the one-way analysis of variance (ANOVA) for different student roles. The analysis shows that the mean value of information giver is higher than information seeker, and there is a significant difference between the mean values ($p < 0.005$). The results indicate that information giver tend to use more words when reflecting their thoughts than the information seeker in discussion forums.

Using a similar approach, we computed the frequency of n-grams in given user posts. We created a vocabulary list using n-grams from lecture transcripts. Then, the study computed the lexical frequency profile (LFP) for each user role. We created a Phrase Matcher Object and applied the matcher object on each user post to extract the keywords. For a given user, the number of keywords used in information giving post increases – reach an optimal number and decreases with time, whereas for information seeking post it increases/decreases with time – also, a minimum level of changes observed in other user post. Moreover, information giver uses more keywords from the lecture transcript than information seeker and other. Further, there is a considerable amount of drop-in ‘other’ user role. Figure 1 shows the Lexical Frequency Profile for a sample of five users with time.

Figure 1: Lexical frequency profile across user role

Information embeddedness is one of the key elements that contribute toward student learning. This study attempts to find the level of information embeddedness using clause extraction. Clause extraction has been used to determine the relationship between the clauses per sentence and language development. We

develop a novel approach in which clauses have been extracted from the parse tree using a rule-based approach. A pipeline is being built with Part-Of-Speech (POS) tagging using Stanford CoreNLP³ to get the basic interpretation of a student post. Tree Annotation is used to extract a parse tree for a given sentence. Initially, clause-level tags (e.g. SBAR) and word-level coordinating conjunction (e.g. CC) have been extracted from the parse tree. Then, we implemented a rule-based approach to extract the number of clauses.

According to Crossley et al. [3], discourse complexity can be measured by any given reading level measures. Therefore, we used Flesch-Kincaid reading level measure to explore discourse complexity with time for each user. Figure 2 demonstrates the discourse complexity for five students with time. The results indicate that if a particular user role can be seen in consecutive posts the level of complexity increases/decreases with minimum change and when there is a role change (e.g. IS \rightarrow IG or IG \rightarrow IS or O \rightarrow IG) there is a dramatic change in discourse complexity.

Figure 2: Discourse complexity across user roles with time

An initial exploratory analysis was performed on topic modelling using state of the art topic modelling technique known as Latent Dirichlet Allocation (LDA). We try to identify the topics that have been discussed in each user post and lecture transcripts. Figure 3 shows the percentage of each topic discussed by information givers and information seekers. According to the analysis, information givers are more involved in discussing the latter part of the course topics than information seekers while information seekers show interest towards the beginning of the lecture content. In future, further analysis will be performed to discover the reasons behind this observed trend.

Moreover, we calculated the affective state of each user posts using LIWC tool. Affect features measures the positive and negative sentiment and more specific emotion such as anger, anxiety and sadness. The results of one-way analysis of variance (ANOVA) show that information seekers express more lexical

³ <https://stanfordnlp.github.io/CoreNLP/>

semantics associated with affective state than information givers. Likewise, we would like to perform several other linguistic experiments to develop a linguistic framework that will demonstrate the linguistic characteristics of different student clusters in discussion forums.

Figure 3: Topic modelling across user role

With the insight gained from existing experiments on user role and linguistic changes, our next step will be to predict the student grading using linguistic-only features. We have done a preliminary analysis on how to divide the student grading into different categories (e.g. pass, fail) and predicted student grades. However, further analysis needs to be performed on feature selection and deploying several other machine learning algorithms to fine-tune the obtained results.

5. CONCLUSION AND FUTURE WORK

The aim of our doctoral work is to understand student learning in MOOCs by investigating user roles and their associated linguistic change. As an initial stage, we have presented a multi-class user role classification in MOOC discussion forums using linguistic-only features with the intention of eliminating the drawbacks (e.g. contextual features) that exist in previous studies. Our model performed well compared to the baseline model, with 82.30 % of F-measure.

As future work, we try to integrate this classification with content and non-content user posts. Thus, it results in a novel classification on user role classification in MOOC discussion forum. On the other hand, our linguistic study gives us a clear differentiation of linguistics aspects associated with each role. Further, we hope to do a meticulous analysis to explore these patterns in future with the intention of discovering the possible reasoning behind the observed trends. Further analysis will be conducted to identify the discourse measures that can contribute to understanding student learning. The study would also like to explore diverse methods/techniques that can discover correlations between these linguistic measures and students' learning in MOOCs. Understanding how these linguistic measures can contribute directly/indirectly to students' learning will help us to propose novel methods to understand students' learning in an online learning environment. In addition, experiments will be performed to identify the correlations between the external factors (e.g. course structure, assignment deadlines) and user role transformations.

As a proof of concept, our technique demonstrated the potential of identifying the linguistic behaviours for each user role. This novel

approach holds a great promise for user role classification and the associated linguistic behaviour in MOOC discussion forums. Additionally, we believe that tracking these role changes and associated linguistic changes will help to understand the student learning in MOOC discussion forums. Thus, this doctoral work, will eventually try to find an answer to 'are students' really learning from MOOCs?'

6. ADVICE SOUGHT

For this doctoral consortium, the study would like advice regarding the following concerns mainly focusing on linguistic study:

1. Discuss language and discourse measures that can contribute to understanding student learning.
2. Discussion on possible reasoning behind the observed trends (e.g. the readability level of the information giver is low (i.e. discourse complexity is high) when compared to the information seeker and other user roles, the level of information embeddedness (number of clauses) is high within the information giver compared to the remaining classes).
3. Discussions on understanding the correlations between external factors (e.g. course structure, learners' demographic) and learner's role (e.g., information seeker, information giver) transformations.
4. Discussions on how existing learning frameworks (e.g. ICAP framework) associate with learner roles.

Building Test Recommender Systems for e-Learning Systems

Oana Maria Teodorescu
University of Craiova
Department of Computer Science
Craiova, Romania
teodorescu_oanamaria@yahoo.com

ABSTRACT

Modern e-Learning systems offer a wide variety of functionalities, from basic ones like accessing courses or online communication to more advanced ones like providing personalized feedback or assets. The learning environment can benefit from recommendations by providing students with tailored learning pathways, or assessment materials, thus ensuring the personalization and adaptation of the e-Learning platform to the student's individual needs. It can also allow for tracking and evaluation of the learner's progress, showing potential for improving the user experience for both students and professors. This research aims to investigate how a recommendation system can be used for building personalized tests in the context of education. The system's main goal is to improve the efficiency of the overall testing activity of learners by recommending questions relative to their knowledge level. It extracts input data based on past test results and uses learning analytics to provide a personal ranking of questions for each student based on their personal and their peers' experience with the studied concepts in a course. Contributions are foreseen on four different levels. First is the design and implementation of the recommendation algorithm. Second, raw data needs to be pre-processed by defining and extracting the features that can be used as input for the recommendation algorithm. Third, a post-processing step is needed for applying data analytics, rules and constraints to the resulted model in order to obtain proper recommendations. Last but not least, the presentation layer must be updated by providing a user interface for students and professors.

Keywords

e-learning; recommender system; user customization

1. INTRODUCTION

Most recommenders aim at providing recommendations to users based on their personal likes and dislikes. These systems use a specific type of information filtering technique

that attempt to recommend information items to the user. In an e-learning environment, both personal and collective information should be taken into account, as well as the links/relationships between the concepts covered in a chapter, as these could provide an insight into the level of knowledge of the student and uncover the missing gaps in the learning process a student is going through for each course.

Using a recommender system, in the context of e-assessments (i.e. online tests), enables the personalization and adaptation of the e-learning platform to the student's individual needs. The information it provides also allows for the tracking and evaluation of a student's progress by both learner and professor. By further analysing it, the information can provide a better understanding and structuring of the material which follows in subsequent chapters, thus providing a more logical chaining of concepts covered for a specific course.

Question recommendations in a test can provide a useful tool in the learning process of students for both the student (through tailored learning paths) and professor (by employing the means of defining and refining learning materials to a more logical and easy-to-understand chain of topics) with a direct impact in the application domain of e-Learning.

2. RELATED RESEARCH

Basic techniques for recommender systems (collaborative, content-based, knowledge-based, and demographic techniques) have known shortcomings such as the well known cold-start problem for collaborative and content-based systems (what to do with new users with few ratings) and the knowledge engineering bottleneck [7] in knowledge-based approaches, as Wikipedia states in [8].

According to an MIT tutorial for SVD (Singular Value Decomposition) [3], calculating the SVD for a matrix M (i.e. finding U and V such that $M = U \times \Sigma \times V$) reduces to finding the eigenvalues and eigenvectors of MM^T and $M^T M$. The eigenvectors of MM^T make up the columns of U , while the eigenvectors of $M^T M$ make up the columns of V . Also, the singular values in Σ are the square roots of eigenvalues from MM^T or $M^T M$. These singular values represent the diagonal entries of the Σ matrix and are arranged in descending order. They are always real numbers. If matrix M is a real matrix, then U and V will also be real.

Recommender systems for e-Learning platforms are based on

Oana Maria Teodorescu "Building Test Recommender Systems for e-Learning Systems" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 810 - 814

many approaches like web mining and information retrieval [4], recommender systems based on the context [13] or even using intelligent agents [14]. One interesting approach of using collaborative filtering in e-Learning systems [2] was to assign greater weights for users with higher knowledge than users with lower knowledge and the authors propose some new equations in the nucleus of the memory-based collaborative filtering. Another interesting paper, presenting clear results regarding recommender systems in smart e-Learning environments shows their approach [9] along with their encouraging results and their aim to extend the system for more faculties.

A concept map or conceptual diagram is a diagram that depicts suggested relationships between concepts, which are defined as “perceived regularities or patterns in events or objects, or records of events or objects, designated by a label” and are depicted as shapes in the diagram [10]. It is a graphical tool that instructional designers, engineers, technical writers, and others use to organize and structure knowledge [6].

3. RESEARCH QUESTIONS

Research questions that need to be addressed are primarily related to the area of recommender systems and selecting the proper recommendations in the context of e-Learning. The main focus is on the actors, which are both learners and professors using the system. The following questions arise:

Q1. How can a recommender system be efficiently used in the context of e-Learning?

A recommender system can give the student personalized tests, find learning gaps and suggest areas of improvement or concept revisions.

What data can a recommender system use as input?

Data from previous usage of the system by the student and his/her peers is required for a good output of the recommender system.

Q2. Are all types of recommender systems “recommended” in e-Learning?

There are majorly six types of recommender systems which work primarily in the Media and Entertainment industry: Collaborative, Content-based, Demographic based, Utility based, Knowledge based and Hybrid recommender system. Which type is better suited for the e-Learning system or how can these types be merged to obtain the most of the recommender for specific target (students of a specific group age, area of study etc.)? This is one of the questions that the research aims to answer.

Q3. How can the recommender system help the student in his/her learning process?

For a student, the recommender system can potentially help the student see his/her current level of knowledge, provide ways of revision and improvement, provide a general indication of the final results before a potential test and assess accumulated knowledge over time.

Q4. How can the recommender system help the professor in the learning process of his/her students?

For a professor, the recommender system can potentially show a student’s progress, point out the difficulties each student has at certain areas of a course and moments when he/she might need a tutor’s help, provide hints on how a student is expected to perform at a test/exam, provide insight on how well the students acquire new concepts based on past ones, identify out-of-order topics or missing information from the course materials.

4. PROPOSED CONTRIBUTIONS

4.1 Research Context

Classical on-line learning environments aim to create a support for learners to get their learning resources and take exams or to be evaluated by the professors; the next learning environments should be more personalized, analyzing each users’ needs and adapting the interface to their concerns and needs. If we consider a usual learning platform, we can say that the learning progress should be considered to be good by the professor for every student, but not all the students have the same needs, nor do they have the same performances at school. A tool that employs a recommender system can create intelligent interfaces capable to adapt to the users’ specific needs, to aggregate learning materials in order to provide the content necessary for the user at that moment and to create an order ranking over the learning materials and among students.

4.2 Research Activities

The main goal of this research proposal is to enhance the effectiveness of the e-Learning environments. In order to achieve this goal, three prerequisites need to be accomplished.

4.2.1 Prerequisites

P1. Analysis and formalization of recommender system’s usage in e-Learning An in-depth study should be conducted in order to assess the way recommender systems are currently used in the e Learning environment. Furthermore, an investigation on new ways to integrate them, along with other information retrieval algorithms for the definition and refinement of the input and output data of the recommended items, into existing e-Learning tools should be made.

P2. Adaptation and definition of data analysis pipelines for input data provided by e-Learning systems A data analysis must be performed on data available for processing in the e-Learning environment in order to filter out unnecessary data, fill in missing information and/or transform it into input data which can be then used by the recommender system. The format of the input data for the recommender system’s algorithm must be defined and updated as the internal processes of the algorithm itself are also updated.

P3. Application and validation of recommender system in student’s and professor’s activity on e-Learning system The aim of the recommender system is to prove itself useful in the context of an e-Learning environment. For this, the recommender system must be integrated in tools that have real application in e-Learning. Upon using and refining its process, a validation must be performed in order to ensure that it provides an increase in productivity of the learning process of the students and the objective evaluation of the professors. For this, certain evaluation methodologies or metrics

have to be devised for a reliable evaluation of the improvements and benefits the new system offers when using the recommender system.

4.2.2 Methodology

Figure 1 presents a generic workflow with 3 main layers and 4 general steps for designing, implementing and validating a recommender system in the context of e-Learning. The division of the system into four steps is inspired by [1] in which the authors propose a framework for an adaptive learning of MOOCs. We identify 3 actors that influence the system: learners (i.e.: students), professors and data analysts.

Data Representation Layer. From this layer, data needs to be gathered. Most systems use a database or log files to keep raw data about users and their activity. The data is taken from this layer and transformed as needed for the recommendation process. This is a layer responsible for providing data input for the Learning Analytics layer. The steps that manipulate data from this layer are the Data gathering and Pre-processing steps. The actors involved in this layer and the associated steps are the data analysts.

Learning Analytics Layer. This layer is responsible for data processing and data analytics, transforming data, defining rules and constraints, preparing data for the algorithms used and applying the final recommendation engine. It communicates with the Data Representation layer for data input and Presentation layer for data output. The specific steps for this layer are the Pre-processing step (for transforming data to the needed format and building data models) and Recommendation step (for employing needed rules, constraints, custom logic and algorithms needed for the recommendation engine). The actors involved in this layer are both data analysts (for building the data model, defining pre-processing logic, rules and constraints, defining and refining the recommendation engine based on experimental results) and users interested in the system (learners and professors) as they are the ones that enforce the domain-level constraints.

Presentation Layer. This layer is responsible with defining the graphical user interface of the system and providing services to the users, such as learner self-testing and online communication (a key feature in modern e-Learning platforms). It communicates with the Learning Analytics layer for data input. The Presentation step is specific to this layer and handles the user interface aspects of the end-user application. The actors involved in this layer are learners and professors which actively use the features of the system.

5. CURRENT STATUS

As research status, three papers have been written so far and an incremental approach is being used to actively improve the recommendation engine based on past results.

In paper [5], which I have co-authored, a custom recommender system based on SVD has been implemented in the context of extending an existing e-learning platform used for distance-education students enrolled in our local university. The recommender has been subsequently tested on students from our university in collaboration with professors for defining the pool of questions and concept maps in the system, with small adjustments being applied after

each year of study. The initial implementation of the recommender, presented in [5], was relying on a collaborative SVD algorithm applied on aggregated test results from all students enrolled in a course. The algorithm selected the proper questions from the available pool of questions, with the only constraints on question repetition and unknown question exploration in case of no questions in the initial aggregation matrix. This approach suffered from the cold-start problem, since it first resulted in generating random recommendation vectors and gradually getting to the desired recommendation mechanism.

Data visualization was implemented in the second paper [11] by building a concept map for the course and assigning concepts to each question in the system. This way, a concept map status could be generated for each student after each test, in which the concept would be colored in red/orange/green to highlight the progress of the student. Greener nodes would indicate that a student is starting to answer most questions in the concept correctly, while redder nodes would indicate that the student answered most questions in the concept incorrectly. Orange nodes were the middle point of the representation, signaling a half-correct distribution of the answers for that concept.

After the first experiment, a custom validation mechanism was implemented, as part of the third paper [12], in which a special function called Correctly Recommended Concepts (CRC) function was implemented. The CRC function was defined as a set of CRC values, plottable for each individual student. A concepts for revision functionality was implemented, which enabled the professor to mark which concepts should be recommended next based on a previous test result of a student. The CRC value was then computed for each test of a student (except the first, for which no revision concept would be defined) as the accuracy of matched concepts by the recommender system relative to the revision concepts, marked by the professor, on a scale of 0 to 1. More specifically, it was computed by dividing the number of matched concepts to the total number of concepts in the test. These values were then plotted for the student on a timeline having the test number on the X axis and CRC value on the Y axis. By observing the slope between tests, the relative performance could be computed by distinguishing 2 main categories of situations: *negative slope* for learners with a lower performance for the student in the next test and *zero or positive slope* for improvements in the performance of the student in the next test.

A second experiment has been conducted, with results to be analysed comparatively for students in a subsequent year of study as part of an incremental approach of improving the system based on results from previous work. The recommendation engine has been refined to consider the order defined in the concept map when choosing questions from the concepts. Also, the cold-start problem has been eliminated by using the old model alongside the new one, as previous test results from the former year have not been deleted from the database and will be used when aggregating input matrix data for the recommender system.

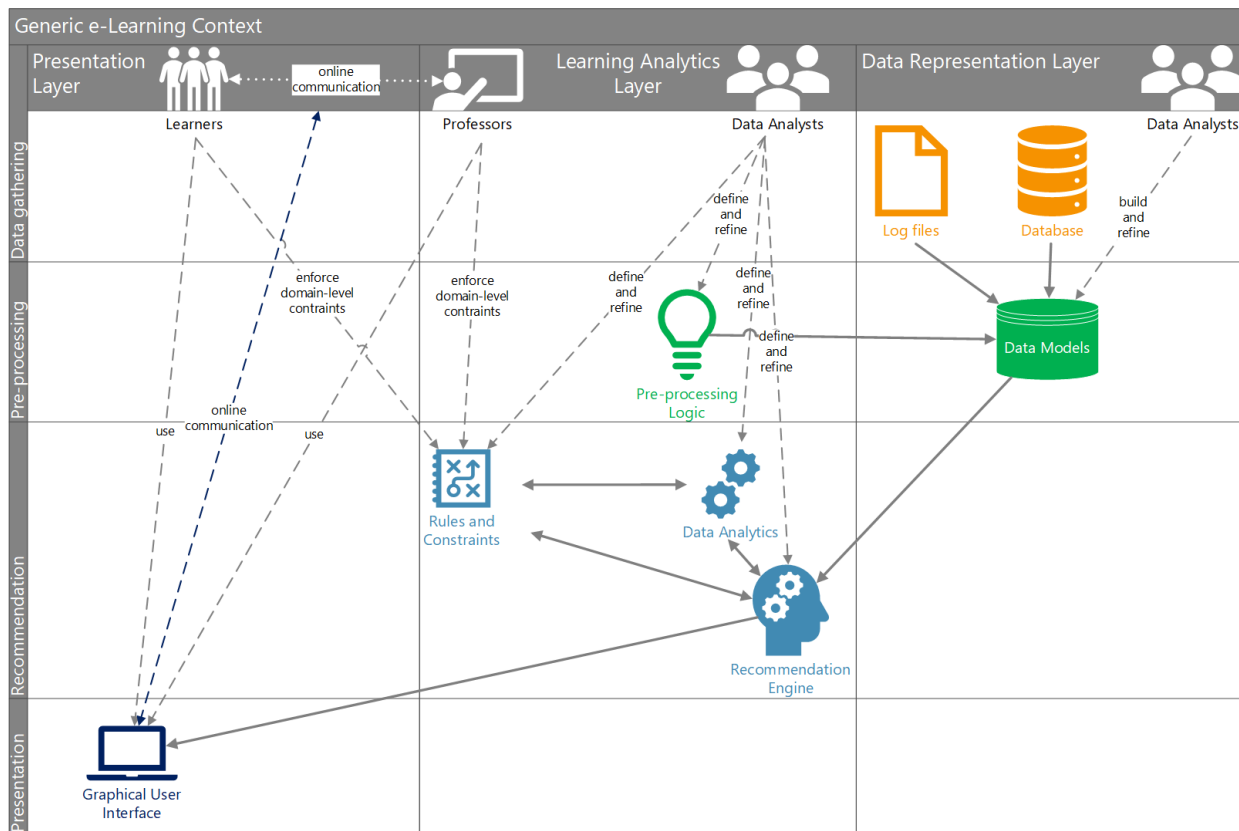

Figure 1: Generic layers and steps for defining a recommendation engine in the context of e-Learning

6. CONCLUSIONS

The main goal of the recommender system is to provide a personalized set of questions depending on both their current status and the status of their peers that have previously taken tests. Visual analytics of the experimental results in terms of knowledge coverage of the concept map show promising initial results.

Future work may regard not only the correctness by which the recommender manages to assign questions from right concepts, but also checking if recommended questions improve the student's learning rate or knowledge level. More work needs to be performed in terms of defining and integrating appropriate quantitative and qualitative metrics for measuring accumulated knowledge with and without the usage of the recommender system. Another future plan is providing the recommender as a software package such that integration into other e-Learning platforms can also be achieved.

Crowd-sourcing and Automatic Generation of Semantic Information in Blended-Learning Environments

Elad Yacobson
Department of Science Teaching
Weizmann Institute of Science
Herzl St 234
Rehovot, Israel
elad.yacobson@weizmann.ac.il

ABSTRACT

Personalized learning environments rely on repositories of digital learning materials, and on meta-data that provides semantic information about the digital content. The semantic information is typically generated by domain experts, but this process is very time consuming, and fails to address the dynamic nature of the content and the contexts in which it is used. In addition, experts may fail to capture semantic properties that are not within their area of expertise. Overall, expert-based semantic generation processes do not scale, and produce limited information. Thus, the goal of my research is to study means to scale and improve the process of collecting and updating semantic information, using two different approaches: crowdsourcing from teachers and learners and automatic tagging that is based on machine-learning algorithms. As a proof-of-concept, two pilot experiments were conducted: the first was with two groups of physics teachers who are using an Open Educational Repository. The main goal was assessing the quality of the semantic information that the teacher-sourcing produces, and factors affecting it. The second experiment aimed at automatic tagging, and focused on comparing several ML approaches to automatically tag learning resources in a K-12 Math online learning environment. In this paper I will present the preliminary findings from these experiments, discuss future directions for my research, and seek advice concerning several issues involved with my research.

Keywords

Personalized Learning, Semantic Information, crowdsourcing

1. INTRODUCTION

Personalized learning environments rely on repositories of digital learning materials (e.g., interactive questions, online labs, videos), and on meta-data that provides rich semantic

information about the digital content. The term ‘semantic information’ refers to information describing the content and different attributes of the online learning resources, such as the topic, the level of difficulty, its intended use - whether as a test, class practice or homework, which grade it is appropriate for, the estimated amount of time required to complete the activity, the technological aids required for it (e.g., a computer, projector, mobile devices), and more.

The semantic information is fundamental to the ability of AI agents to make ‘intelligent’ decisions such as recommending content to learners, to assist teachers in search & discovery of learning resources, and for re-using and sharing materials between contexts [1, 2, 3]. However, while high-quality digital content is in many cases readily available on the web, it is the semantic information that is usually missing, inadequate, or partial. Thus, having scalable processes for generating high-quality semantic information can contribute significantly to the development of personalized learning environments.

Semantic information is typically generated by domain experts, but this process is very time consuming, and the experts may fail to capture semantic properties that are not within their area of expertise [5]. In addition, the content repository and the context in which it is used are dynamic, requiring frequent revisions and updates. Overall, expert-based semantic generation processes do not scale, and produce limited information. My research aims to address these issues, by studying means to produce semantic information at scale, as detailed in the next section.

2. RESEARCH DIRECTIONS

The high-level goal of my research is to study two main approaches for collecting and updating semantic information: The first is crowdsourcing (more accurately: teacher- and learner-sourcing, which are the terms that are used hereafter), and the second is automatic tagging using machine learning algorithms. More specifically, this goal is further divided into the following issues:

Semantic Information Required. The first issue that I want to examine is what types of semantic information assist teachers in search & discovery of educational resources in open repositories. With the transfer of a growing number of

Elad Yacobson "Crowd-sourcing and Automatic Generation of Semantic Information in Blended-Learning Environments" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 815 - 817

teachers to blended learning, teachers often rely on learning resources found online. These resources are commonly organized in Open Educational Repositories (OER) that offer teachers a large pool of instructional materials. For teachers, selecting appropriate and effective instructional materials from an OER is a challenging and time-consuming process. Thus, I wish to explore what semantic information is required for supporting teachers in this process.

Sources for Obtaining Semantic Information. As aforementioned, I will focus on two approaches for obtaining semantic information about the learning resources: crowdsourcing from teachers and learners, and automatic tagging that is based on ML algorithms. I will compare two aspects of the information obtained from these approaches: the accuracy of the information, and coverage – how much information can be obtained from each of these sources.

Factors That Affect the Quality of Teacher and Learner-Sourced Information. The goal of this research direction is to study the different factors that affect the quality of teachers and learner-sourced semantic information. I will address both the issue of teachers' and learners' *ability* to accurately tag learning resources with semantic information, and their *motivation* to do so. In terms of ability, I will study issues and task definitions that support accurate tagging. For instance, can teachers and students tag resources without having full knowledge of the taxonomy from which the tags are taken? to which resolution do teachers and learners need to go in analyzing the questions in order to provide accurate tags? The second issue is teachers and learners motivation to contribute time and effort to tagging, as this is a time-consuming and cognitively demanding process, with no perceived reward. Providing incentives for crowdsourcing is a known issue [4], and it is reasonable to assume that engaging teachers and learners in crowdsourcing would require appropriate incentive design.

Effect of Tagging Process on Teachers and Learners. The last aspect of crowdsourcing that I wish to examine is the effect (if there is any) of the tagging process on teachers' professional development, and on students' learning. With respect to teachers, I will focus on the effect of participation on their ability to provide personalized learning and adapt tasks to individual needs of different students. With respect to learners, I intend to focus on whether the reflective nature of the tagging process contributes to student understanding, as reflective processes has been repeatedly shown to improve learning.

3. PRELIMINARY RESULTS

To date, two pilot experiments were conducted, each addressing a different approach for obtaining semantic information. The first experiment was held with two groups of Physics teachers. The teachers were requested to tag questions taken from a blended-learning environment named *PeTeL* (described below), and their tagging was compared to that of domain experts. In the second experiment, a supervised machine-learning approach was applied to ~ 400

activities taken from a Math learning environment named *STEP* (see below), which are tagged according to different dimensions, such as their topic (Geometry, Algebra, Verbal Problems, Infinitesimal Calculus etc.)

3.1 First Experiment - Teacher Sourcing

The first experiment was designed as a proof-of-concept for teachers' ability to accurately tag learning resources with semantic information. The participating teachers were requested to tag questions taken from a learning unit on Magnetism according to a detailed taxonomy prepared by a group of expert teachers and researchers.

Learning Environment - PeTeL. The experimental setup is based on a learning environment named PeTeL, which is both an OER, and an LMS that also includes social network features and learning analytics tools. It is developed within the Department of Science Teaching at Weizmann Institute of Science, with the goal of providing STEM teachers with a blended learning environment for personalized instruction. PeTeL is divided into separate modules for each subject matter: Biology, Chemistry and Physics. The Physics module is currently being used by approximately 200 teachers and 7000 high school students. All the teachers who participated in the experiment use PeTeL in their classes.

Procedure and Results. Two groups of Physics teachers participated in this experiment. The first group consisted of eight teachers who were presented each with three questions from PeTeL. Each question contains a picture or diagram of a certain Physics situation (e.g. a particle moving through a magnetic field, or an electric circuit), and a question regarding that diagram (See example in Figure 1). For each question i , the teachers were presented with four tags. Then, for each tag, the teachers were requested to decide whether it applies to i . Overall, we received 95 responses. In 74 out of 95 responses, the teachers agreed with the domain expert as to whether the content knowledge described in the tag is required for solving the question (78% agreement, Cohen's kappa: 0.56).

A rectangular frame with sides a and b , is shown in the following diagram. An electric current is flowing through each of the frame's sides in counter-clockwise direction. The frame is located in a magnetic field entering the page's plain, as shown in the diagram.

- * what is the direction of the magnetic force working on side a of the frame?
- * what is the direction of the magnetic force working on side b of the frame?
- * what is the direction of the magnetic force working on side c of the frame?
- * what is the direction of the magnetic force working on side d of the frame?

Does solving this question require the following concepts?

- * The magnetic field creates a force over a current-carrying wire - yes / no
- * Effect of different parameters on the force: magnitude of magnetic field and of current - yes / no
- * The magnetic force's direction is vertical to the direction of the magnetic field and to the direction of electric charges - yes / no
- * Effect of different parameters on the force: the angle between the direction of the field and the direction of the current - yes / no

Figure 1: Tagging Task Example

The second part of the experiment took place about a month after the first one, with a different group of seven Physics teachers, and followed a similar protocol. A total of 56 responses were collected. In 43 out of 56 responses, the teachers agreed with the domain expert as to whether the content knowledge described in the tag was required for solving the questions (77% agreement, Cohen's kappa: 0.54).

3.2 Second Experiment - Automatic Tagging

The second experiment was conducted in the context of STEP, an OER for junior-high and high-school Math, which was developed by the Department of Math Education in the University of Haifa.

Procedure. 407 learning activities were taken from STEP. Fifty keywords were selected as features (e.g., 'angle', 'function', 'speed', 'derivative', 'linear', 'sinus', etc.). Each activity was encoded as a one-hot vector according to the presence of these keywords, and labeled with its Math topic (Geometry, Algebra, Verbal Problems, etc.). Then, three ML algorithms (Naive Bayes, Random Forest, and Logistic Regression) were applied to the data in an attempt to evaluate the feasibility of classifying activities into topics based on these features.

Results. Measured with k-fold cross-validation, the accuracy of the classification produced by the ML algorithms was 95% (achieved by the Naive Bayes and the Random Forest algorithms).

3.3 Conclusions

The results of these two small-scale experiments suggest that regarding teacher-sourcing, when the tagging task is formulated in a certain way (e.g., "yes/no" questions), teachers can tag items relatively accurately (Cohen's kappa: 0.56) without being trained on the taxonomy from which the tags are taken. Regarding automatic tagging by ML algorithms, these preliminary results are encouraging as to the ability to produce quality semantic information without the need for human intervention.

On the next step, we intend to run these experiment on a larger scale, using a technological tool to teacher-source semantic information from a much larger pool of teachers, to expand our work to learner-sourcing as well, and to apply learning algorithms to a multitude of learning resources in an attempt to reach much more fine-grained semantic information.

4. PROPOSED CONTRIBUTION

I hope that my work will have both a practical contribution to the learning environments that I study, and through this, to teaching and learning, and will contribute to EDM research by providing a better understanding of effective means to enrich learning environments with semantic information.

5. DISCUSSION AND ADVICE SOUGHT

I seek advice regarding four major issues in my research: the first is *what are the most effective means to enhance teachers' and learners' motivation to invest time and effort*

in the tagging process? In this regard, since we saw indications that teachers' motivation affects the quality of their tagging, I feel that positive incentives, rather than negative ones (e.g., requiring participation for receiving access to materials) are more likely to produce quality results.

The second issue is *how to optimize the relationship between coverage (i.e. how many tags are requested from each teacher or learner) and motivation.* On one hand, presenting the teacher/learner with numerous requests for tagging could easily deter him/her and would result in low rates of participation. On the other hand, minimizing the interaction with the user would result in low coverage.

The third aspect is how to evaluate the quality of the semantic information received from teachers and learners? After receiving tags produced by either teachers or learners, there is the question of how reliable those tags are. Possible solutions are random evaluation by an expert, or wisdom-of-the-crowd based ranking solutions.

And last, regarding the process of automatic tagging – a main challenge is abstracting different types of information representation (text, figures, symbols) into a common layer of semantic meaning, probably relying on NLP, object recognition, etc. I would appreciate receiving information regarding relevant research that I can build upon.

The Learner Data Institute: Big Data, Research Challenges, & Science Convergence in Educational Data Science

EDM 2020 Workshop Description

Vasile Rus

University of Memphis

vrus@memphis.edu

Stephen E. Fancsali

Carnegie Learning, Inc.

sfancsali@carnegielearning.com

ABSTRACT

We describe a half-day online workshop for researchers interested in learning about—and contributing to—the work of the Learner Data Institute (LDI), an initiative funded by the U.S. National Science Foundation (NSF) and based at the Institute for Intelligent Systems, University of Memphis, in collaboration with Carnegie Learning, Inc., and other partners. LDI's mission is to foster and support science convergence to address major challenges in learning with technology (online and blended) through an expanding, global network of expert panels, school-based practitioners, interdisciplinary research teams, and task-oriented special interest groups. Founding members of the LDI have been working together to plan mechanisms and processes for building shared understanding, and for exploring methods of extracting and packaging actionable knowledge from the massive datasets generated by current computer-supported instructional systems and from the stores of text, sound, graphics, video, and other data modalities that are rapidly accumulating on cloud-based servers around the world. The community at large is invited to participate in the workshop to hear about our work, help us refine our ideas through paper and talk contributions, and explore how they too can become involved in this important new enterprise.

Keywords

big data in education, educational data science, educational data mining, learning analytics, educational technology, science convergence, interdisciplinary research, trans-disciplinary research, multi-disciplinary research.

1. WORKSHOP DESCRIPTION

1.1 Interdisciplinary solutions

Historically, the proceedings of the *International Conference on Educational Data Mining* (and related conferences, including the *International Conference on Artificial Intelligence in Education*, the *ACM Conference on Learning at Scale*, and *Learning Analytics and Knowledge*) demonstrate inherent linkages across traditional and emerging academic disciplines and research areas. Vasile Rus and Stephen Fancsali "The Learner Data Institute: Big Data, Research Challenges, and Science Convergence in Educational Data Science." In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*. Anna N. Rafferty, Jacob Whitehill, Violetta Cavallari-Storza, and Cristobal Romero (eds.) 2020, pp. 818 - 820

as, but not limited to, psychology, economics, cognitive and learning science(s), mathematics, computer science (e.g., machine learning, artificial intelligence), statistics, human-computer interaction, public policy, education, neuroscience, social work, moral and political philosophy, and any of a number of sub-fields and research areas at the intersection of these disciplines.

The need for such multi/inter/trans-disciplinary solutions is even more relevant today as the vast and diverse repositories of digital data available can make such solutions viable. Indeed, recognizing both substantial scientific challenges and the need for innovative scientific frameworks to solve them, the U.S. National Science Foundation has identified the notion of “convergence” research as one of ten “big ideas” for its on-going investment strategy [1]. Two attributes are crucial to NSF’s notion of convergence research [2], namely that such research is “driven by a specific and compelling problem” and emphasizes “deep integration across disciplines.” Such integration is achieved when:

“...experts from different disciplines pursue common research challenges, [and] their knowledge, theories, methods, data, research communities and languages become increasingly intermingled or integrated. New frameworks, paradigms or even disciplines can form sustained interactions across multiple communities” [2].

The NSF-funded Learner Data Institute (LDI) focuses on such science convergence solutions for major challenges in learning with technology (online and blended). Furthermore, LDI will contribute to at least two of the ten new Big Ideas for Future Investment announced by NSF: Harnessing the Data Revolution for 21st Century Science and Engineering (HDR) and The Future of Work at the Human-Technology Frontier (FW-HTF).

1.2 The Learner Data Institute

LDI is an NSF-funded “data-intensive research in science and engineering” (DIRSE) initiative seeking to set out compelling, specific, big data research challenges for educational data science researchers and large-scale scientific and data convergence approaches to address them.

The LDI will help us learn: (1) how to transform a far-flung group of interdisciplinary researchers, developers, and practitioners into

a community of practice that can fully exploit the data revolution through data and science convergence; (2) how adaptive instructional systems and data science can be used as research vehicles to further our understanding of how learners learn; (3) to explore the human-technology partnership with data and data science to improve learners' and teachers' ability to employ technology in a way that facilitates learning, while at the same time improving the affordability, effectiveness, scalability of these systems; and (4) more generally, how to extend the frontiers of data science to include: new methods of data collection and design; more interpretable machine learning methods (e.g., by combining deep learning with more interpretable inference frameworks like Markov Logic); scalable new algorithms (e.g., for joint inference in Markov Logic Networks); and methods for identifying causal mechanisms from unstructured, semi-structured, and structured data.

More specifically, LDI contributors from university-based research groups, industry, and government are focusing on cutting-edge, big data approaches to *assessment, learner modeling, instructional design, modeling subject-area domains in instructionally useful ways, socio-cultural aspects of learning, ethical aspects of working with learner data, and the human-technology frontier*, among other areas of interest.

Approximately 40 LDI contributors were recently surveyed as a part of the initiative to envision the future of convergence research in educational data science; they were asked to identify areas of challenge and societal need with respect to improving education and learning, compelling opportunities, and ways in which big data can be harnessed to address both. Portions of this workshop will be devoted to presenting and discussing the findings of this survey. In addition, the workshop convenes a diverse set of researchers and developers, some associated with LDI and others not, working with big data from contexts in which learning takes place, seeking to better understand state-of-the-art interdisciplinary research as well as compelling, specific societal needs and challenges and the scientific, big data frameworks that might be leveraged to solve them in the future.

We expect that this convening of a diverse, highly experienced group of researchers will stimulate substantial growth and interest in the notion of science convergence, including helping to set the direction of the LDI and the framework that it is tasked by NSF with developing.

2. WORKSHOP FORMAT

The half-day workshop will take the form of an introductory talk introducing the LDI, presenting results of the LDI contributor survey, and situating those results within the goals of LDI and the broader notion of convergence research for educational data science. Two invited speakers will deliver keynote talks (including Q&A) laying out their visions for convergence research in educational data science, situating this idea within their individual research program(s), and/or discussing the results of the LDI survey. A selection of peer-reviewed contributed research papers (generally concerned with state-of-the-art big data methodology, applications, and research in educational data science, ideally with an emphasis on science convergence) and/or position papers (on similar topics with an eye toward where future research *should* be directed) will also be presented as a part of the workshop. A panel discussion will also take place, involving a moderator, keynote speakers, and 1-3 invited contributors.

3. SCHEDULE

The half-day workshop will include introductory remarks presenting an overview of the LDI as well as its recent survey/envisioning results, two invited keynote talks, and several presentations from selected paper submissions and/or invited contributors from LDI and the broader community at large. Time will be allotted for Q&A for each presentation as well as a panel discussion given sufficient time.

4. SPEAKERS

4.1 Overview of the LDI Mission, Activities, & Accomplishments: Vasile Rus, University of Memphis, Department of Computer Science & Institute for Intelligent Systems

Vasile Rus, William Dunavant Professor of Computer Science and Institute for Intelligent Systems, University of Memphis, will provide the introductory presentation and is Lead Principal Investigator of the Learner Data Institute. His research, funded by NSF, the U.S. Department of Education Institute for Education Sciences, the Office of Naval Research, and other funding agencies, centers on topics of natural language processing and understanding, including semantic similarity, question answering, and knowledge representation, especially with applications to adaptive instructional systems and software defect knowledge management. Before joining the University of Memphis, Dr. Rus received a Ph.D. in Computer Science at Southern Methodist University and was an Assistant Professor of Computer Science at Indiana University.

4.2 LDI – The Developer and Practitioner Perspective: Stephen E. Fancsali, Carnegie Learning, Inc.

Stephen E. Fancsali is Director of Advanced Analytics at Carnegie Learning, Inc., and Co-PI of the Learner Data Institute. His work focuses on statistical and causal modeling using data from adaptive systems for learning like Carnegie Learning's *MATHia* intelligent tutoring system (formerly *Cognitive Tutor*). This work includes developing practical progress monitoring metrics usable by teachers and learners in K-12 classrooms, statistical early warning systems that indicate when students are struggling unproductively, causal modeling of learner behavior, and scaling up semi-automated methods for improving cognitive models that underlie such adaptive learning systems to produce deployable instructional improvements. Before joining Carnegie Learning, Inc., he received a Ph.D. in Logic, Computation, & Methodology at Carnegie Mellon University.

4.3 Invited Keynote Speaker: Jason Hartline, Northwestern University, Department of Computer Science

4.3.1 Keynote Abstract

The talk will provide an overview of a peer grading system that is under development at Northwestern U. In courses that use the system it has (a) reduced the grading load of course staff by over 75%, (b) expanded and improved the students' interaction with the course material, and (c) improved turn-around time of feedback on student work (students receive comments on their work after three days, rather than two weeks). As a research platform, this system enables a dialogue between theory and practice for algorithms, machine learning, data science, and mechanism design. Of particular focus for the talk is on

mechanisms that incentivize peers to produce accurate reviews and the connection between these mechanisms and auction theory.

4.3.2 Keynote Speaker Biography

Jason Hartline is a professor of computer science at Northwestern University and a co-director of the Institute for Data, Econometrics, Algorithms, and Learning (IDEAL). His research introduces design and analysis methodologies from computer science to understand and improve outcomes of economic systems. Optimal behavior and outcomes in complex environments are complex and, therefore, should not be expected; instead, the theory of approximation can show that simple and natural behaviors are approximately optimal in complex environments. This approach is applied to auction theory and mechanism design in his graduate textbook *Mechanism Design and Approximation*, which is under preparation (<http://jasonhartline.com/MDnA/>). Professor Hartline received his Ph.D. in 2003 from the University of Washington under the supervision of Anna Karlin. He was a postdoctoral fellow at Carnegie Mellon University under the supervision of Avrim Blum and subsequently a researcher at Microsoft Research in Silicon Valley. He joined Northwestern University in 2008.

4.4 Invited Keynote Speaker: Carolyn Penstein Rosé, Carnegie Mellon University, Language Technologies Institute & Human-Computer Interaction Institute – “Towards Computer-Supported Collaborative Learning in the Workplace Enabled by Language Technologies”

4.4.1 Keynote Abstract

Well meaning companies offer training opportunities to their employees, but when push comes to shove, companies are known to push for short-term productivity over learning and higher productivity in the long term. The practical goal of the research is to enable learning during work, with a focus on software development teams.

Building on over a decade of AI-enabled collaborative learning experiences in the classroom and online, in this talk we report our work in progress beginning with classroom studies in large online software courses with substantial teamwork components. Project courses provide an effective test bed to begin our investigations due to similar tensions imposed by the reward structure. Project courses are believed to be valuable experiences for students to engage in reflection on concepts while applying them in practice. However there is a concern that the reward structure encourages students to engage in performance oriented behaviors, such as the most capable student taking on the lion's share of the work while leaving the others behind. These behaviors undercut the opportunity to use the project experience for each student to gain practice and for the students to reflect together on underlying concepts. In our classroom work, we have adapted an industry

standard team practice referred to as Mob Programming into a paradigm called Online Mob Programming (OMP) for the purpose of encouraging teams to reflect on concepts and share work in the midst of their project experience. At the core of this work are process mining technologies that enable real time monitoring and just-in-time support for learning during productive work. This talk will offer an overview of a series of classroom studies and introduce a corpus available through Learnsphere.org's DiscourseDB facilities:

<https://erebor.lti.cs.cmu.edu/discoursedb/index.html>.

4.4.2 Keynote Speaker Biography

Dr. Carolyn Rosé is a Professor of Language Technologies and Human-Computer Interaction in the School of Computer Science at Carnegie Mellon University. Her research program is focused on better understanding the social and pragmatic nature of conversation, and using this understanding to build computational systems that can improve the efficacy of conversation between people, and between people and computers. In order to pursue these goals, she invokes approaches from computational discourse analysis and text mining, conversational agents, and computer supported collaborative learning. Her research group's highly interdisciplinary work, published in over 240 peer reviewed publications, is represented in the top venues in 5 fields: namely, Language Technologies, Learning Sciences, Cognitive Science, Educational Technology, and Human-Computer Interaction, with awards in 3 of these fields. She is a Past President and Inaugural Fellow of the International Society of the Learning Sciences, Senior member of IEEE, Founding Chair of the International Alliance to Advance Learning in the Digital Era, and Co-Editor-in-Chief of the *International Journal of Computer-Supported Collaborative Learning*. She is a 2020-2021 AAAS Fellow under the Leshner Institute for Public Engagement with Science, with a focus on public engagement with Artificial Intelligence.

An Introduction to Neural Networks

Agathe Merceron
Beuth University of Applied Sciences Berlin
merceron@beuth-hochschule.de

Ange Tato
Université du Québec à Montréal
nyamen_tato.ange_adrienne@uqam.ca

ABSTRACT

In this tutorial, participants explore the fundamentals of feedforward neural networks such as the backpropagation mechanism and Long Short Term Memory neural networks. The tutorial also covers the basis of Deep Knowledge Tracing, the attention mechanism and the application of neural networks in education. There will be some hands-on applications on open educational datasets. The participants should leave the tutorial with the ability to use neural networks in their research.

A laptop capable of installing and running RapidMiner, Python and the Keras library is required for full participation in this tutorial.

Keywords

Neurons, Neural networks, LSTM, Attention mechanism.

1. INTRODUCTION

Neural networks (NN) are as old as the relatively young history of computer science: McCulloch and Pitts already proposed nets of abstract neurons in 1943 as Haigh and Priestley report in [5]. However, their successful use, especially under the form of convolutional neural networks (CNN) or Long Short Term Memory (LSTM) neural networks, in areas such as image recognition and language translation in the last years have made them widely known, also in the Educational Data Mining (EDM) community. This is reflected in the contributions that are published each year in the proceedings of the conference.

The upper green curve labeled “Neural Networks + LSTM” of Figure 1 shows the percentage of contributions (long and short papers, posters & demos, young research track, doctoral consortium, and papers of the industry track) that have used some kind of neural networks in their research while Table 2 -at the end of this paper- shows in the column “Total” the number of these contributions. Contributions that mention neural networks in the related works or future works only are not counted. One notices two jumps: in 2016 and 2019; the total goes from two to ten and then from 16 to 32 while the number of contributions goes from 147 to 132 and then from 112 to 139. This shows that neural networks are becoming more and more important in our field. In Figure 1, the blue curve “Neural Networks + no LSTM” gives the percentage of the contributions that have used neural networks other than LSTM neural networks, simply called LSTM in the following, while the orange curve “LSTM” shows the percentage of papers that have used LSTM in their research (these contributions might have used LSTM and also other kinds of neural networks). Till 2015, the green curve and the blue curve overlap, as there is no contribution using LSTM. In Table 2, the International Conference on Educational Data Mining (EDM 2020), Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 821 - 823

columns “Neural Network” and “LSTM” give the numbers instead of the percentages.

Figure1. Evolution over the years of the percentage of contributions using neural networks in the EDM proceedings.

Recognizing the growing importance of neural networks in the EDM community (see Figure 1 and Table 2), this tutorial aims to provide 1) an introduction to neural networks in general and to LSTM neural networks with a focus on the attention mechanism, and 2) a discussion venue on these exciting techniques. This tutorial targets 1) participants who have no or very little prior knowledge about neural networks and would like to use them in their future work or would like to better understand the work of others, and 2) participants interested in exchanging and discussing their experience with the use of neural networks.

A simple kind of neural network is a feedforward neural network also often called a multilayer perceptron. It propagates the calculation of each neuron from its inputs through all layers in a directed way forward to its outputs. In education, such NN are often used to predict the performance of students. The work of Romero et al. [12] presented at the first EDM conference in 2008 use them to predict the final mark of students in a course taught with the support of the learning platform Moodle.

While their primary use was in Natural Language Processing (NLP) Tasks, LSTM have recently been used in education and have achieved remarkable results [17, 16]. Opposed to feedforward neural networks that cannot remember the past, LSTM have cycles and are a kind of recurrent neural network. The LSTM [6] architecture can learn long-term dependencies using a memory cell that can preserve states over long periods. It is suitable for contexts where sequential information and temporal prediction is important such as in education, where we are interested in the prediction of students' outcome based on past

behavior. Deep Knowledge Tracing [8] is probably the best example of using LSTM to track students' knowledge states while they interact with a tutoring system. Numerous variants of LSTM have been proposed, such as the Gated Recurrent Unit (GRU) [3], or the LSTMs with Attention.

Attention [2] in machine learning refers to a model's ability to focus on specific elements in data. It helps the LSTM to learn where to look in the data. It was initially designed in the context of Neural Machine Translation using sequence to sequence (Seq2Seq or encoder-decoder) [13] models. However, since the attention mechanism can improve prediction results of NN models, it is now widely used in text mining in general. Especially in the education domain, it has been used for questions answering tasks, sequential modeling for student performance prediction or to predict essay or short answer scoring [18, 11].

2. THE TUTORIAL

2.1 Schedule

Table 1. Tutorial schedule

Time	Item
45 minutes	Introduction - Feedforward neural networks and backpropagation
45 minutes	Application - Discussion - Hands-on with RapidMiner
30 minutes	Break
60 minutes	LSTM and Attention Mechanism
60 minutes	Application - Implementation of a LSTM for student performance prediction - Discussion

2.2 Introduction to feedforward neural networks

This part begins with artificial neurons and their structure - inputs, weight, output, and the activation function - and the calculations that are feasible and not feasible with one neuron only. It continues with feedforward neural networks or multi-layer perceptrons (MLP). A hands-on example taken from [7] illustrates how a feedforward neural network calculates its output.

Further, this part introduces the backpropagation algorithms and makes clear what a feedforward neural network learns. Backpropagation is demonstrated with the hands-on example introduced before.

2.3 Application

This part discusses the use of feedforward neural networks in EDM research. These networks are often used to predict students' performance and students at-risk of dropping out, see for example [4, 1, 15]. However, other uses emerge. For example, Ren et al. use them to model the influence on the grade of course taken by a student of all other courses that the student has co-taken [10].

The main activity of this part is for participants to create, inspect, and evaluate a feedforward neural network with the free version of the tool RapidMiner Studio [9]. The data that will be used

comes from a German university. The task is to predict whether a student will drop out of a degree program. RapidMiner Studio is a graphical tool for Data Science which requires no programming. The tool will be introduced and participants will learn to load data, explore them, and classify them with neural networks. In particular, the following steps will be covered: discovering the operators "Neural Net" and "AutoMLP", cross-validation, models comparison, and grid optimization of the parameters with RapidMiner. Processes will be provided so that participants do not have to design them from scratch and can learn more efficiently.

2.4 LSTM

In this part of the tutorial, basic concepts of LSTM are covered. We will focus on how the different elements (cell, state, etc.) of the architecture work. Participants will learn how to use an LSTM for the prediction of learners' outcomes in an educational system. Concepts such as the Deep Knowledge Tracing (DKT) will be also covered.

2.5 Attention Mechanism

In this part, the attention mechanism is introduced. Participants will learn how this mechanism works and how to use it in different cases. We will explore concepts such as global and local attention in neural networks.

2.6 Application

In this hands-on part, we will explore existing real-life applications of LSTM (especially Deep Knowledge Tracing) in education. We will also explore the combination of LSTM with Expert Knowledge (using the attention mechanism) for Predicting Socio-Moral Reasoning skills [14]. Participants will implement an LSTM with an attention mechanism for the prediction of students' performance in a tutoring system. We will use Python especially the Keras library for coding. We will also use open educational datasets (e.g. Assisments benchmark dataset).

3. OBJECTIVES AND OUTCOMES

The objectives of this tutorial are twofold: 1) introduce the fundamental concepts and algorithms of neural networks to newcomers, and then build on these fundamentals to give them some understanding of LSTM and the attention mechanism; 2) provide a place to discuss and exchange about experiences while using neural networks with educational data.

Newcomers should leave the tutorial with a good understanding of neural networks and the ability to use them in their own research or to appreciate better research works that use neural networks. Participants already knowledgeable about neural networks get a chance to discuss and share about this topic and connect with others.

A website will be created to display important information to participants: schedule, slides, data, software to download and install.

Table 2. Number of contributions using neural networks in the EDM proceedings

Year	Neural Network	LSTM	Total	Number Contributions
2008	1	0	1	31

2009	2	0	2	33
2010	2	0	2	64
2011	1	0	1	67
2012	1	0	1	49
2013	4	0	4	98
2014	3	0	3	120
2015	2	0	2	147
2016	4	6	10	132
2017	7	6	13	98
2018	6	10	16	112
2019	19	19	38	139

exposed to LearnSphere from these past events, although we will have some tutorial activities included for new attendees as well. This workshop builds off a successful LAK 2018 Tutorial, workshop at AIED/EDM 2017, and workshops at EDM 2019.

2. ORGANIZATIONAL DETAILS

2.1 Type of Event

Workshop

2.2 Proposed Schedule

Table 1. Proposed Half-day Schedule

Time	Item
8:30	Introductions
9:00	Tigris workflow tool (Lecture & Demos)
10:10	Coffee Break
10:20	Hands on: Build custom analysis workflows using existing Tigris components
11:20	5-minute participant talks about proposed or created workflows
12:00	Closing / High-level Discussion

2.3 Type of Participation

Mixed participation will be through submission of reviewed abstracts, invited guests, and open registration. For participants who have accepted abstracts or are invited by the workshop committee, we have allocated approximately \$15,000 from our grant funding to cover registration and some travel costs of select participants based on quality of submissions, attract students and junior faculty, and a goal to create a diverse set of participants.

2.4 Activities

Activities will include presentations from workshop organizers, invited guests, and short presentations from accepted abstract presenters. Hands on sessions will include demos and group work towards implementing analytics.

2.5 Expected Numbers

We expect 15-20 participants based on previous workshops.

2.6 Activities to Recruit Attendees

We will create a website to announce the workshop and method of submitting abstracts. The Learning Analytics, Educational Data Mining, and LearnLab mailing lists will be used to direct potential attendees to the workshop website. In addition, we will include a number of invited guests. Both accepted submissions and invited guests will have the chance to receive funding to attend.

2.7 Required Equipment

Projector and screen will be required by organizers. Attendees will need to bring laptops and will need adequate internet connectivity.

3. OBJECTIVES AND OUTCOMES

Broadly, this workshop offers those in the Learning Analytics community an exposure to LearnSphere as a community-based

infrastructure for educational data and analysis tools. In opening lectures, the organizers will discuss the way LearnSphere connects data silos across universities and its unique capabilities for sharing data, models, analysis workflows, and visualizations while maintaining confidentiality.

More specifically, we propose to focus on attracting, integrating, and discussing researcher contributions to Tigris, the web-based workflow authoring and sharing tool. Workshop submissions in the form of abstracts will involve a brief description of an analysis pipeline relevant to modeling educational data as well as accompanying code. Prior to the workshop itself, the organizers will coordinate with authors of accepted submissions to integrate their code into Tigris. A significant portion of the workshop will be dedicated to hands-on exploration of custom workflows and workflow modules within Tigris. Authors of accepted submissions will present their analysis pipelines, and everyone attending the workshop will be able to access those analysis pipelines within Tigris to a variety of freely available educational datasets available from LearnSphere. The goal is to generate -- for each workflow component contribution in the workshop -- a publishable workshop paper that describes the outcomes of openly sharing the analysis with the research community.

Finally, workshop attendees will discuss bottlenecks that remain toward our goal of a unified repository. We will also brainstorm possible solutions. Our goal is to create the building blocks to allow groups of researchers to integrate their data with other researchers we can advance the learning sciences as harnessing and sharing big data has done for other fields.

ABSTRACT

There is a growing community of researchers at the intersection of data mining, AI and computing education research. The objective of the CSEDM workshop is to facilitate a discussion among this research community, with a focus on how data mining can be uniquely applied in computing education research. For example, what new techniques are needed to analyze program code and CS log data? How do results from CS education inform our analysis of this data? The workshop is meant to be an interdisciplinary event at the intersection of EDM and Computing Education Research. Researchers, faculty and students are encouraged to share their AI- and data-driven approaches, methodologies and experiences where data is transforming the way students learn Computer Science (CS) skills. This full-day workshop will feature a panel, paper presentations, discussions to promote collaboration, and a kick-off of the 2nd CSEDM Data Challenge.

Keywords

Computer Science Education, Educational Data Mining, AI in Education, Learning Analytics

1. WORKSHOP GOALS

Computing is an increasingly fundamental skill for students across disciplines. It enables them to solve complex, real and challenging problems and make a positive impact in the world. Yet, the field of computing education is still facing a range of problems from high failure and attrition rates, to challenges training and recruiting teachers, to the underrepresentation of women and students of color.

Advanced learning technologies, which use data and AI to improve student learning outcomes, have the potential to address these problems. However, the domain of CS education presents novel challenges for applying these techniques.

CS presents domain-specific challenges, such as helping students effectively use tools like compilers and debuggers, and supporting complex, open-ended problems with many possible solutions. CS also presents unique opportunities for developing learning technologies, such as abundant and rich log data, including code traces that capture each detail of how students' solutions evolved over time.

These domain-specific challenge and opportunities suggest the need for a specialized community of researchers, working at the intersection of AI, data-mining and computing education research. The goal of this 4th Educational Data Mining for Computer Science Education (CSEDM) workshop¹ is to bring this community together to share insights for how to support and understand learning in the domain of CS using data. This field is nascent but growing, with researching in computing education increasingly using data analysis approaches, and researchers in the EDM community increasing studying CS datasets. This workshop will help these researchers learn from each other, and develop the growing sub-field of CSEDM.

The CSEDM workshop is co-organized with CS-SPLICE (cssplice.org), an NSF-funded organization that seeks to build infrastructure for intelligent learning content in CS education. The workshop will build on three successful prior CSEDM workshops at: 1) the International Educational Data Mining Conference (EDM) in 2018², 2) the International Learning Analytics and Knowledge Conference (LAK) in 2019³, and 3) and the International Conference on AI in Education (AIED) in 2019⁴. Each were fruitful and well-attended. We hope to keep our momentum with a 4th CSEDM Workshop, returning to EDM in 2020. We also build on the success of 5 prior SPLICE workshops at CS education conferences (ACM SIGCSE, ACM ICER).

1.1 Relevant Topics

The workshop encourages contributions from the following topics of interest:

- Predictive and descriptive modelling for CS courses

¹sites.google.com/ncsu.edu/csedm-ws-edm-2020/

²sites.google.com/asu.edu/csedm-ws-edm-2018/

³sites.google.com/asu.edu/csedm-ws-lak-2019/

⁴sites.google.com/asu.edu/csedm-ws-aied-2019/

Thomas Price, Peter Brusilovsky, Sharon Hsiao, Kenneth Koedinger and Yang Shi "Educational Data Mining in Computer Science Education (CSEDM) Workshop" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 826 - 828

- Adaptation and personalization within CS learning environments
- Intelligent support for collaborative CS problem solving
- Machine learning approaches to analyze massive CS datasets and courses
- Online learning environments for CS: implementation, design and best practices
- Multimodal learning analytics and combination of student data sources in CS Education
- Affective, emotional and motivational aspects related to CS learning
- Adaptive feedback, adaptive testing for CS learning
- Discourse and dialogue research related to classroom, online, collaborative, or one-on-one learning of CS
- Peer-review, peer-grading and peer-feedback in CS
- Teaching approaches using AI tools
- Visual Learning Analytics and Dashboards for CS
- Network Analysis for programming learning environments
- Self-Regulated learning for CS environments
- Writing and syntax analysis for programming design learning
- Natural Language Processing for CS forums and discussions
- Analysis of programming design and trajectory paths
- Recommender systems and in-course recommendations for CS learning

We will invite researchers who are interested in further exploring, contributing, collaborating and developing data- and AI-driven techniques for building educational tools for Computer Science to submit paper on any of these topics.

2. WORKSHOP ORGANIZATION

The workshop will be organized by a team with a history of CSEDM research:

Thomas Price is an Assistant Professor of Computer Science at North Carolina State University. His primary research goal is to develop learning environments that automatically support students through AI and data-driven help features. His work has focused on the domain of computing education, where he has developed techniques for automatically generating programming hints and feedback for students in real-time by leveraging student data. He has helped organized a number of efforts at the intersection of AIED, Data Mining and CS Education, including the CS-SPLICE working group on programming snapshot representation and prior CSEDM and CS-SPLICE workshops.

Peter Brusilovsky is a Professor of Information Science and Intelligent Systems at the University of Pittsburgh, where he also directs Personalized Adaptive Web Systems (PAWS) lab. He has been working in the field of adaptive educational systems, user modeling, and intelligent user interfaces for more than 30 years. He published numerous papers and

edited several books on adaptive hypermedia and the adaptive Web. He is a founder of CS-SPLICE and has advanced research and infrastructure for CSEDM.

Sharon I-Han Hsiao is an Assistant Professor at the School of Computing, Informatics & Decision Systems Engineering in Arizona State University. Her research lies in the intersections of Informatics & Computational Technologies for Learning with a focus on Intelligent Tutoring Systems, Computer Science Education, Adaptive Educational Systems, Open User Modeling, Data Sciences, Visualization, Social Computing, and Learning Technologies.

Ken Koedinger is Professor of Human-Computer Interaction and Psychology at Carnegie Mellon. He explores how people think and learn by developing and studying technology-enhanced learning. He leads the LearnSphere effort (learnsphere.org), which integrates learning data and analytics across multiple resources. And he directs LearnLab (learnlab.org), which started with 10 years of National Science Foundation funding and is now the scientific arm of CMU's Simon Initiative (cmu.edu/simon). He is also a founder of CS-SPLICE.

Yang Shi is a PhD student at North Carolina State University. His research focuses on developing data-driven methods for representing program code to enhance the ability of intelligent learning environment to support students and model their learning. Yang's research interest includes CSEDM, Automatic Hint Generation, Programming Language Processing, Software Representations, Software Analysis and Deep Learning.

2.1 Program Committee

The 4th CSEDM Workshop's program committee includes:

- Austin Cory Bart (University of Delaware, USA)
- Barbara Ericson (University of Michigan, USA)
- Petri Ihantola (University of Helsinki, Finland)
- Juho Leinonen (University of Helsinki, Finland)
- Cliff Shaffer (Virginia Tech University, USA)
- Alan Smeaton (Dublin City University, Ireland)
- Sergey Sosnovsky (Utrecht University, Netherlands)
- John Stamper (Carnegie Mellon University, USA)
- Michael Yudelson (ACT)

3. CALL FOR PARTICIPATION

We will solicit two types of research contributions:

4-8 page Research Papers: Original, unpublished work or work-in-progress, addressing any of the topics of interest above.

2-4 page Presentation Abstracts: Researchers will present their work at CSEDM in a conversational format. Presentations might include:

- Descriptions of shareable Computer Science (CS) datasets

- Descriptions of data mining / analytics approaches applied to specifically Computer Science datasets
- Descriptions of tools or programming environments that use/produce data
- Case studies of collaboration where reproducible practices were used to integrate or compose two or more data analysis tools from different teams
- Descriptions of infrastructures that could collect and integrate data from multiple learning tools (e.g. forum posts, LMS activity and programming data)

4. WORKSHOP ACTIVITIES

The workshop will be a **half day** workshop, held online on July 10th, 2020. It will primarily consist of paper presentations, discussions to facilitate collaboration, and a kickoff of the 2nd CSEDM Data Challenge. The full schedule can be found at the workshop website: sites.google.com/ncsu.edu/csedm-ws-edm-2020

4.1 2nd CSEDM Data Challenge – Kickoff

A unique aspect of the CSEDM workshops is the CSEDM Data Challenge. The goal of this challenge is to bring researchers together to tackle a common data mining task that is specific to CS Education. We are building on the success of the first CSEDM Data Challenge⁵. The first challenge focused on the task of modeling students' programming knowledge in order to predict their performance on future tasks. Researchers competed to build the best predictive model, using a common dataset. This year, we will use the CSEDM workshop to kick off a second Data Challenge. Our goal is to use the workshop as a space to build researcher interest in the challenge, introduce the datasets to be used, and get input from the community on their goals for the challenge.

5. SOLICITATION PLAN

Building on our growing network of contributors to prior workshops, we intend to solicit participation on the workshop through the following mailing lists and research networks:

- ACM's Special Interest Group on Computer Science Education (SIGCSE)
- Computer Science Education (CSED) research list (from the ICER community)
- European Association of Technology-Enhanced Learning (EATEL) community
- User Modeling (UM) mailing list
- Asia-Pacific Society for Computers in Education (AP-SCE) community
- PSLC community list
- Relevant EU project consortia
- The International Educational Data Mining Society
- The Society for Learning Analytics Research (SoLAR)

⁵github.com/thomaswp/CSEDM2019-Data-Challenge

Causal Inference in Educational Data Mining

Half-day workshop

EDM 2020

Fully Virtual

1. OVERVIEW

The goal in crafting intelligent tutoring systems, educational games, MOOCs, and other computerized learning tools, is to improve student learning. To that end, EDM research typically focuses on methods to identify, measure, and predict learner behaviors or outcomes. Causal research seeks to estimate the impacts of different factors on these behaviors or outcomes—not only predicting who will wheel-spin, experience frustration, or successfully learn a new skill, say, but determining causes these? Causality lies at the heart of both learning science, which seeks to understand how inputs in an educational system affect the system’s outputs, and of policy, which seeks to design educational systems that improve learning.

The field of causal inference, which spans statistics, philosophy, economics, computer science, and other more traditional academic disciplines, has itself experienced rapid and exciting developments in the recent past. The new science of causality encompasses new ways of estimating effects under challenging circumstances, such as possible confounding, but also new questions—how do impacts vary between learners? What mechanisms drive causal effects? How may we construct optimal individualized policies for specific learners?

This workshop is intended to raise awareness of the ubiquity and importance of causal questions in EDM, some of the exciting methods available to address those questions, and some of the open questions of causal inference in EDM. It will include invited discussions of ongoing projects addressing causal questions, and short talks about relevant work in progress, including work in any stage of development.

Lastly, the workshop will give an opportunity for EDM researchers to submit open problem related to causality in EDM research, in an exercise motivated by the Quantitative Methods Program seminar at the University of Michigan Institute for Social Research. In five minute presentations, researchers will briefly present problems they have encountered

in research, or that they just think are interesting, but that they do not yet know how to solve. Each presentation will be followed by an open-ended discussion among the workshop participants, hopefully suggesting ways to solve, or at least better refine the problem. This sub-workshop will hopefully give the presenting researchers constructive suggestions, and spur collaborations.

In general, the workshop will be organized to stimulate discussion among participants, including, hopefully, constructive suggestions for open problems.

2. TOPICS OF INTEREST

We will solicit work on topics including, but not limited to:

- A/B Testing
- Graphical causal models/Bayesian networks
- Analyzing data from randomized experiments
- Multi-armed bandits
- Investigations of causal mechanism/mediation analysis
- Estimating EDM program impacts
- Identifying and predicting differential effects
- Connections between machine learning and causal inference
- Dynamic treatment regimes
- Principal stratification
- Causal inference in EDM without randomization

3. ORGANIZERS

- Adam Sales (University of Texas, Austin/Worcester Polytechnic Institute)
- Stephen Fancsali (Carnegie Learning)
- Anthony Botelho (Worcester Polytechnic Institute)
- Joseph Jay Williams (University of Toronto)
- Neil Heffernan (Worcester Polytechnic Institute)

Adam Sales "Workshop: Causal Inference in Educational Data Mining" In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 829 - 830

0:00-0:30	Introduction: Causal questions in EDM (Adam Sales)
0:30-1:30	Two long (20 minute) talks, with discussion
1:30-2:15	Three talks describing work in progress (10 minutes each), with discussion
2:15-3:15	Open problems workshop
3:15-3:30	concluding discussion

Table 1: Preliminary Schedule

4. IMPORTANT DATES

- Submission deadline (Extended): Monday, June 15, 2020
- Acceptance notification (Extended): Monday, June 29, 2020

Reviewing process: The workshop organizers will review papers, alongside external reviewers whose expertise is appropriate for the submissions. These may include Anna Rafferty (Carleton College), Thanaporn March Patikorn (Worcester Polytechnic Institute), Peter Schaldenbrand (Carnegie Mellon University) and others.

ABSTRACT

This document outlines a proposed full-day workshop focused on the intersection of fairness, accountability, transparency, and educational data mining (EDM). The workshop aims to provide a multidisciplinary perspective on fairness-related work from both “sides” of the EDM community (*education* and *data mining*) along with other relevant fields (human–computer interaction, machine learning, etc.). Our workshop aims to be an inclusive opportunity for EDM researchers to learn about an emerging field, as well as to define a research agenda for this area of critical importance to the field.

1. BACKGROUND

As data-driven algorithms are increasingly relied upon to shape user experiences, deliver content, and make decisions across a variety of domains, concerns have grown around the fairness, equity, accountability, transparency, and inclusivity of algorithmic systems and the broader pipelines within which they exist (e.g., training data, human decisions made using algorithmic outputs). The field of educational data mining, being concerned with the use of data about human

subjects for the purposes of studying educational processes and improving learning outcomes, is intimately tied to these concerns about fairness, accountability, and transparency.

On the other hand, equity is at the heart of the development goals of education across the globe, given the personal, economic and social benefits of education [26]. Accordingly, decades of education research have been devoted to understanding existing inequities and finding ways to address them [11, 5]. Concerns around fairness in data mining used in educational contexts must therefore be viewed in the broader context of educational concerns around equity. In fact, early work on fairness in educational testing dating back to the 1960s preempted many contemporary definitions of fairness that have emerged in the machine learning (ML) literature [16].

Because this cluster of topics¹ is still an emerging field both within the EDM community and the broader field of data mining, we believe that it is the responsibility of EDM researchers to be at the forefront of defining the future research of such a field, and to incorporate FATE-related inquiries into their work. Towards this ends, this document describes a full-day workshop to explore the intersection of fairness research (broadly construed) and educational data mining. We propose a “bidirectional” approach, wherein the workshop focuses both on synthesizing past research as well as defining an agenda for future work in the field. Our or-

Nigel Bosch, Christopher Brooks, Shayan Doroudi, Josh Gardner, Kenneth Holstein and Renzhe Yu “FATED: Fairness, Accountability, and Transparency in Educational Data (Mining)” In: *Proceedings of The 13th International Conference on Educational Data Mining (EDM 2020)*, Anna N. Rafferty, Jacob Whitehill, Violetta Cavalli-Sforza, and Cristobal Romero (eds.) 2020, pp. 831 - 834

¹As an emerging subfield, the area of Fairness, Accountability, Transparency (and often also Ethics) does not have a single agreed-upon name; in this document, we use the term “FATE” to refer to these topics jointly.

ganizing committee draws from a broad set of disciplinary backgrounds, including machine learning, human-computer interaction (HCI), and education, and we intend the workshop to serve as a unifying forum for a variety of research and disciplinary perspectives.

We believe that the proposed workshop will provide a firm foundation for participants to conduct future impactful FATE-related EDM research by providing both a foundation in past work and a well-defined set of research goals for future work to address. Furthermore, we believe that this workshop will serve to advance the EDM2020 theme, “Improving Learning Outcomes for All Learners.”

2. PRIOR WORK

This section does not attempt to provide an exhaustive list of work relevant to the workshop. Instead, it is intended to provide a sense of the work in this area which we hope to introduce to participants and build upon in our intended outcomes.

2.1 FATE in Data Mining and ML

Over the past decade, a rich subfield of fairness research has emerged within the data mining and machine learning communities. Research has investigated the (un)fairness of data mining and machine learning algorithms applied to several different applications, including image classification [8] and natural language processing [6]. Additionally, there is a rich and ever-growing body of literature on methods and metrics for fair data mining and machine learning [3]. This has also included research into the biases inherent to data itself, as our workshop title implies. Finally, work has also begun to explore the relationship between the utility, fairness, and privacy of statistical models [19, 18], all of which are critical to the success of educational models in certain contexts [15].

While several conferences and other publication venues have emerged to share research related to fairness² as well as subgroup-specific venues for advancing such work within specific subfields³, EDM has not yet offered a workshop to address such topics directly.⁴

2.2 Equity in Education

Educational equity and achievement gaps are topics that have been studied by education researchers and have been of paramount importance to the practice of education for generations [11]. Empirical research in the past few decades have found consistent evidence of systematic gaps in educational opportunities and outcomes by socioeconomic status, immigration status and gender [5]. Of relevance to educational data mining, [16] surveys several notions of testing-related fairness in education and employment, demonstrating that several recent conceptions of fairness were anticipated in prior works as early as the 1960s. In the context of educational technology, a number of studies have shown

³See e.g. Fair ML for Health <https://www.fairmlforhealth.com/>

⁴For a related effort, see <https://sites.google.com/view/fairlak>.

that even with equal access, more privileged students may disproportionately benefit from technologies than less privileged or marginalized students, often due to socio-cultural factors [24]. Relatedly, recent work on online learning has found that usage patterns vary by demographic groups in diverse global learning environments [14] and that identity-based interventions have disparate impact in adaptive learning environments [7, 21]. Work on fairness in EDM should situate itself in the context of this broader work on educational equity. One of the goals of this workshop will be to bring voices from educational researchers to help ensure a desirable path forward for FATE in EDM.

2.3 Fairness in EDM

Within the EDM community, some earlier research has investigated the generalizability of student models to new student populations and/or learning contexts (aka *external validity*) but found mixed results [2, 25]. While this investigation remains a critical research direction of EDM research [1], the fairness perspective speaks more to the *internal validity* of data mining models. Towards this end, recent research in educational data mining and learning analytics has evaluated the fairness of on-time graduation models [17], mastery learning algorithms in tutoring systems [12], dropout models in MOOCs [13], and the effects of perceived AI (un)fairness in college admissions [23]. Combined with the influence of socio-cultural factors as mentioned above, these works collectively suggest that the ways in which fairness-related issues intersect with the methods and goals of educational data mining systems are complex, multidimensional, and in need of further research.

2.4 Transparency in EDM

Data mining is often integrated into educational systems to automate or enhance decision-making processes that might otherwise be performed by humans, such as homework grading [10] or personalizing learning content [4]. Automated decision-making may affect students in large ways (e.g., automatic homework grading assigning a failing grade) as well as relatively minor ways (e.g., selecting the next topic of study), though even minor effects may accumulate into large outcomes. For students, teachers, and other stakeholders to trust decisions made by data mining algorithms, it is essential that those algorithms provide transparent explanations of their decision-making process at an appropriate level [20].

However, even simple models such as linear regression with a few variables or Bayesian knowledge tracing [9] can be difficult for many users to understand [22]. Previous work has explored the possibility of creating explanations specifically for Bayesian knowledge tracing [27], and found a great deal of heterogeneity in the level of explanation needed across users (e.g., students), as well as the desire different users had for an explanation. Given that the difficulty of creating and selecting an appropriate explanation is enhanced by factors such as age, native language, and neurodiversity that vary across individuals, this is a large area of potential research that we propose to discuss and define with respect to educational data mining in this workshop.

3. WORKSHOP STRUCTURE

We propose a “bidirectional” workshop structure, with a backward-looking component focused on synthesis of both

historical and state-of-the-art work, as well as a forward-looking component focused on defining a research agenda for the field.

3.1 Backward-Looking Activities

The backward-looking component will be focused on bringing together a comprehensive and multidisciplinary view of how to measure, identify, and correct for lack of fairness in fields relevant to educational data mining research. Given that there has been an explosion of work on fairness in machine learning over the past few years, it can be difficult for researchers to begin working in this literature without getting lost. Rather than providing a broad tutorial of all definitions and approaches to fairness, we aim to provide an introduction that more thoroughly examines a smaller set of approaches and recent discussions relevant to the field of educational data mining. We intend for this section to include a mix of presenter-led synthesis presentations as well as participant-led presentations (invited or submitted) providing perspectives from specific research studies. The goal for this component is to provide a firm foundation in the state of the field for interested researchers, including those new to fairness-related research.

3.2 Forward-Looking Activities

The forward-looking component will be focused on identifying measures of success, key open problems, and a research agenda for the emerging work in fairness for educational data mining. This section will be largely participant-driven. One possible activity for this section is a reverse assumptions activity (a method from HCI and UX design), wherein participants iteratively construct “positive” and “negative” design fictions for fairness-related research in EDM. In this way, we can not only pinpoint concrete ways in which unfairness can creep into well-intentioned solutions (negative design fictions), but also identify solutions that can mitigate concerns around fairness and equity (positive design fictions). Finally, we aim to conduct work on a collaborative document providing a taxonomy of fairness-related work in EDM and a list of open problems to focus efforts in the field. We will facilitate these activities through a series of brainstorming activities that will consist of individual idea generation, synthesis and refinement of ideas via group discussion, and subsequent group work toward formalizing and expanding ideas through groups formed around interest in specific ideas.

4. INTENDED OUTCOMES

Our intended outcomes for this workshop are twofold. First, we aim to provide a foundation for workshop participants in prior fairness-related work relevant to the EDM community. The resources used for this component of the workshop will be made available open-source, and we hope that this will support the larger EDM community and provide a catalyst for future learning. Second, we aim to provide a set of concrete community-created resources for fairness-related work in EDM. These include the results of our design fictions activities, definitions of open problems in the field, and a taxonomy to direct future research efforts in this burgeoning subfield. These outputs will be disseminated to the broader educational data mining community. Ultimately, the long-term goal of this workshop is not to create a niche commu-

nity of EDM researchers interested in fairness, accountability, and transparency, but to encourage all researchers and practitioners in the EDM community to think about how to ensure FATE in the work they do.
